Market Concentration and Business Cycles

Abstract

How does market concentration affects business cycles? We build a model featuring the dynamic competition between a forward-looking large firm and a continuum of heterogeneous entrepreneurs who are financially constrained. The elasticity of demand of the large firm is endogenously determined by the strategic competition. We find that the effect of the strategic competition is non-monotonic. It is conditional on how does a shock alter the market power of the large firm and, hence, how does her markup respond to the shock. Although the endogenous markup mitigates shocks on large firms, it significantly amplifies shocks that are biased to entrepreneurs such as credit crunches. Furthermore, for homogeneous productivity shocks, due to financial frictions, entrepreneurs are more cyclically sensitive. Consequently, the strategic competition amplifies the aggregate decline in output while accelerates the recovery. The increasing in concentration dampens homogeneous productivity shocks because large firms are more productive. Yet, the markup of large firms is more responsive, which offsets the effect of the higher productivity by a half. We show that the strategic competition distorts the optimal subsidization by amplifying the welfare cost of implementing the subsidy. The predictions of the model are consistent with the Compustat data.
1 Introduction

With the increasing trend of the market concentration in the United States, many research have explored the implications of the concentration on the economic dynamics (see, e.g. Dorn et al. (2017), Autor et al. (2020), Wang and Werning (2020)), and highlighted the intrinsic differences between the small and the large firms (e.g. Crouzet and Mehrotra (2020), Caglio et al. (2021)). Yet, the researches studying the relation between market concentration and business cycle are largely missing. What are the implications of the concentration on economic fluctuations? How does the concentration distorts the optimal stabilization policy? To answer the questions, we study the business cycles and optimal policy interventions with a model featuring the strategic competition between a large firm and competitive entrepreneurs that are financially constrained.

We find that the implications of the strategic competition on business cycles are non-monotonic: it is conditional on how does the shock change the market power and, therefore, the markup of the large firm. We find that the subsidization policy is by its nature benefiting the large firm, since her marginal cost is more elastic to factor prices. As a result, the welfare cost to implement the policy is amplified since the raised markup suppresses the wage. The study suggests that the more detailed and agent-specific policies should be applied to minimize the the distortions on the labor demand. The predictions of the model are consistent with the empirical evidence from the Compustat data.

The economy we study is composed of a continuum of sectors. Within each sector, based on the timing of the dominant firm model by Gowrisankaran and Holmes (2004), we assume that there exists dynamic Stackelberg price competitions between a large firm who plays as a leader, and a continuum of competitive entrepreneurs behaving like followers. We generalize their framework by assuming that the competitive entrepreneurs are financially constrained and are heterogeneous in wealth and productivity as in Buera and Moll (2015). Taken prices as given, the competitive entrepreneurs choose not only choose the amount to produce, but also the amount to save in order to finance the capital investment in future. Anticipating the saving and the supply of the competitive entrepreneurs, the forward-looking large firm optimizes the pricing strategy to maximize her lifetime value based on the current states and independent with the histories.

In the model, the elasticity of the demand of the large firms are endogenously determined by the strategic competition. Similar to the demand system imposed by the Kimball aggregator as in Boar and Midrigan (2019), the model has the property that the static elasticity of demand of the leader is a decreasing function with respective to her market share. Additionally, because of financial frictions, the forward-looking leader internalizes that her pricing strategy has dynamic effects on the wealth accumulation of the followers, which affects the demand of the leader in future. Therefore, in aggregate, the elasticity of demand for the leader is compound. It is consisted of the static elasticity and the dynamic elasticity of demand, where the latter is the discounted present value of the influence of the pricing strategy on the large firm’s demand in future. By proposing a tractable framework, the model provides a specific micro-foundation for the demand system, which gives new insights into how does the firms’ markup endogenously evolve along with business cycles.

To elucidate the mechanism through which the endogenous markup influences the fluctuations of
the economy, we set a benchmark model with the isomorphic framework except that the large firms behave monopolistic competitively and charge the constant markup. We evaluate the dynamics of the economy of the both models after the same productivity shocks. By comparing the differences in resource allocations, pricing strategies and responses in optimal policies across the two models, we illuminate the implications of the strategic competition on business cycles.

We find that the effect of the strategic competition is non-monotonic and depends on how does the shock alters the market power of the leaders and, therefore, how does the markup respond to the shock. Specifically, we isolate the two effects, the direct effect and the transitional effect, that the endogenous markup has on the economic dynamics. Note that due to financial frictions, a transitory shock could have long-lasting effect by undermining the strength of the balance sheet of the firms. The transitional effect represents the implication of the endogenous markup by altering the wealth accumulation of the constrained firms. In further, the closed-form analysis reveals that the two effects are contradictory. The direct effect of the increasing markup amplifies the shock by raising the efficiency wedge. Yet, the raised markup accelerates the recovery by increasing the relative demand and thus the profits of the entrepreneurs. The quantitative analysis shows that the direct effect always dominates.

We generalize our analysis by quantitatively evaluating the dynamics of the economy with standard shocks, e.g. credit crunches, TFP shocks. We find that throughout the whole dynamic transitions, because of financial frictions, the followers are more sensitive to the shocks than the large firms. Consequently, the endogenous markup amplifies the aggregate decline of the economy yet accelerates the speed of convergence. In further, we explore the implication of the deepening of concentration by separately calibrating the productivity of the leader, so that the more productive leader has the higher market share at steady state. In aggregate, we find the deepening of concentration mitigates the shocks because the resources are re-allocated to the more productive leaders. However, the effect of the endogenous markup is more significant too. Because the markup is more elastic to the elasticity of demand when the leader has higher market share. Accordingly, if not take the endogenous markup into consideration, we would overestimate the effect of the increasing concentration on the fluctuations of the economy by two times.

To investigate the policy implications of the strategic competition, we evaluate the optimal intervention of interest rate subsidization to stabilize the economy after a negative shock on the wealth of entrepreneurs as Itskhoki and Moll (2019)\(^1\). We draw two main lessons from the experiments of the uniform interest cut. First, consistent with Ottonello and Winberry (2020), we find that the large firms benefit more from the uniform subsidization, since they are unconstrained and, therefore, their marginal cost is more elastic to the factor prices. Second, the strategic competition distorts the optimal policy by suppressing the wage and thus increasing the welfare cost on the households, which implies that the government should apply more-detailed and agent-specific interventions that is targeted on the constrained. We in further evaluate the optimal interest rate cut that is biased to

\(^1\)Itsikhoki and Moll (2019) discussed the optimal development policy to subsidize labor supply within a competitive framework where the economy starting from the initial state such that the wealth of entrepreneurs are way below than steady state level; while our analysis of business cycle focuses on the minor deviations of the wealth of followers.
the entrepreneurs. Compared to the uniform interest cut, the biased policy enables a higher welfare improvement. Yet, because of the strategic competition, the policy maker should be conservative on the interest rate cut during the crisis. Because the endogenous markup dampens the subsidization to the entrepreneurs by distorting resource allocations and raising the equilibrium wage.

We test the two main predictions of the model: the shock is amplified when it increases the market share of the leader; yet in the long run, the same type of the shock accelerates the recovery and the wealth accumulation of the followers. We test the predictions with the Compustat data. More specifically, we define the large firms as the top 2 firms of each sector in NAICS 6-digit level to match the market share of the large firms defined by Crouzet and Mehrotra (2020). We confirm the effect in the short run by validating that there exists a statistically significant negative relation between the increase of the market share of the large firms and the demeaned growth rate of the sales of the sector. We validate the long run implication from the two dimensions: between-crisis and within-crisis. We first compare the dynamics between the recent three crises after 2000. We find that, accompanied with a more persistent decline in the liability and the income of the small firms, the crisis where the large firms are relatively more impacted features a slower recovery process. Furthermore, we test the relation within the period of the financial crisis. Within-crisis, we confirm the prediction of the model by documenting the significant positive relation between the increase of the market share of the large firms and the future growth rate of the equity and the income of the followers.

1.1 Literature Review

Our study is related to the series of papers exploring the macroeconomic implications of concentration in the product market. On the side of the macroeconomics, the mainstream modeling of market concentration is based on the combination of the Kimball aggregator and monopolistic competitions to guarantee that the elasticity of demand is a decreasing function of the market share. Therefore the aggregator imposes the specific demand system such that the firms with the greater market shares endogenously charge higher markup. Boar and Midrigan (2019) evaluates the aggregate and distributional impact of product market interventions in a model featuring the concentration in wealth and firm ownership. Baqee and Farhi (2020) and Edmond et al. (2018) investigate how does the increase in the size of the market affects welfare and GDP. Although the aggregator is flexible to the market structure and therefore has the great capability to fit the data, we lose the insights behind the different pricing strategies across the firms exactly because of the convenience the aggregator brings. In contrast, our paper provides a particular micro-foundation in a tractable framework that features the dynamic strategic competition, which helps us to establish the intuitions and to bridge the gap between the model and the real world.

Conversely, the papers modeling the concentration with strategic competitions are mostly established on the structure of the duopoly game. Chen et al. (2020) explores the implications of competition-distress feedback effect on asset prices and financial contagion with a model where two firms compete over customer bases. Mongey et al. (2017) combines nominal rigidity with duopoly
competitions and finds that the output responses to monetary shocks are much higher compared to the monopolistic competition. Olmstead-Rumsey (2019) builds a model based on the structure of duopoly game in creative destruction to explain the raising of the concentration in United States around 2000. Although the deep insights they bring to the macro dynamics, the papers omit the other important component of the economy, the small competitive firms. By contrast, we are focusing on the competition between the dominant firms and the competitive small firms, which are quantitatively important by constituting the other half of the economy and have the distinct pricing strategies compared to the market leaders.

Furthermore, because of financial frictions, we think that it is also qualitatively important to highlight the strategic competition between the small and the large firms is of great importance in exploring the implications of concentration on business cycle, especially in studying the propagation of the shocks. Starting by Gertler and Bernanke (1989), it is widely studied that a transitory shock could have long-lasting effects by undermining the strength of the balance sheet of the firms (see else, e.g. Bernanke et al. (1999), Brunnermeier and Sannikov (2014), Brunnermeier et al. (2012)). Given that the small firms are more financially constrained and more sensitive to the monetary shocks, (e.g. Chodorow-Reich et al. (2021), Caglio et al. (2021)), the strategic competitions between the small and the large firms can have serious implications on the process of rebuilding the balance sheet after crisis and thus altering the macro dynamics in the recovery process. Deviating from the traditional competitive framework in the literature of financial frictions, the paper contributes to the literature on exploring the macroeconomic implications of financial frictions on business cycle by evaluating the effects of strategic pricing on the process of the wealth accumulations of the constrained entrepreneurs.

Our work is related to the strand of literature that highlights the differences in the fluctuations between the small and large firms around the business cycle. Starting from Gertler and Gilchrist (1994), many has explored the firms’ responses to shocks are heterogeneous in size. Kudlyak and Sanchez (2016) uses public QFR data to show that the large firms’ short-term debt and sales contracts relatively more than that of the small firms in the Great Recession. Crouzet and Mehrotra (2020) documents that the cyclicality of sales and investment are declining with firm size with the confidential QFR data. The strand of the research implies that the business cycle has heterogeneous effects on the firms with different sizes. Therefore, the market power of the dominant firms, or the market concentration itself is evolving over the business cycle. By contrast, our work contributes to the literature by exploring the implication of the cyclical evolution of market concentration on business cycle and the propagation of crisis.

The paper is also related to the literature studies the optimal policy intervention with financial frictions. Our work is closely related to Itskhoiki and Moll (2019) where they studies optimal development policy to subsidize the constrained entrepreneurs in the transition dynamics where the economy starts from an initial state with the wealth of the entrepreneurs below its steady state value. They find that it is optimal to increase labor supply in the initial phase of transition when the financial wealth low enough. By contrast, we are focusing on the optimal intervention
with minor deviation of the wealth around the steady state. Boar and Midrigan (2019) evaluate various steady state policy and find that optimal regulation improves allocative efficiency, thereby increasing product market concentration. Conversely, our analysis investigates the stabilization policy and focuses on how does the optimal policy response is distorted by the concentration. In further, different from their work, we emphasizes the cost to implement the policy is increasing with concentration, since the raised markup of dominant firms suppresses the wage. Bianchi (2016) analyzes the trade-off of bailout policies between the ex-post welfare improvement and ex-ante risk-taking. In contrast to their work, we study the ex-post improvement while focusing on the distortion from the concentration.

In terms of methodology, following Atkeson and Burstein (2008) and Wang and Werning (2020) we formulate a model where the economy is consisted of a continuum of sectors, while within each sector, by applying the idea of the dominant firm model by Gowrisankaran and Holmes (2004), we introduce the dynamics strategic competition over prices between the dominant firm and competitive fringes. Corbae and D’Erasmo (2019) applies the same structure of the strategic competition to the banking sector to study the financial regulation. Different from their work, we focus on the implications of the concentration of the product market on business cycle. Incorporating the idea of the intrinsic differences in the outputs of the large and small firms by Holmes and Stevens (2014), we assume that the elasticity of substitution between the large and small firms is lower than that within the products of the small firms, which is a crucial assumption for the closed form characterization. Finally, given the documented fact that the small firms are more constrained (e.g. Chodorow-Reich et al. (2021), Caglio et al. (2021)), following Buera and Moll (2015) and Itskhoki and Moll (2019), the financial friction is introduced as the leverage constraint applied only to the competitive entrepreneurs.

The remaining part of the paper proceeds as follows. Section 2 illustrates the basic statistics related to the market structure of the United States and the correlation between the concentration and business cycles. Section 3 describes the model. Section 4 analytically characterizes the dynamics of the economy after impulse shocks. Section 5 quantifies the model and displays numerical experiments. Section 6 explores the policy implications and section 7 contains empirical studies. Finally, section 8 concludes the paper.

2 Basic statistics

In this section we show three main facts that motivate our research and modeling choices, including the concentrated product market of the United States, the differentiated financial conditions across firm size, and the evolution of market concentration along with business cycles.

Table 1 from Crouzet and Mehrotra (2020) documents the high degree of skewness in the distribution of sales and growth of firms across the whole economy using the confidential QFR data. The top 0.5% of firms have assets of 6 billion and sales of 1.5 billion which are roughly 10 times greater than the firms with size between 99% to 99.5%. Meanwhile, the average asset and sales of
firms within the bottom 90% of the size distribution are less than thousandth of that of market leaders. Similarly, there exists a significant trend of concentration within sectors. Table 2 displays the within-sector share of sales by size group where the sector is defined in 6-digit level. According to the Census 2012, on average, there are more than 700 firms within each sector while 42% of the market is taken by top 4 firms. By contrast, firms of top 5 to 50 own another 40% and the last 20% of the market belongs to the left 650 firms. The statistics suggest that ordered by assets, the marginal market share of firms declines very quickly even within-sector, implying a market structure with the coexistence of very few dominant firms and a large amount of small firms.

Table 3 presents an overview of the financial statistics provided by Crouzet and Mehrotra (2020). Compared to the top 0.5% firms, the firms within the bottom 90% of the assets distribution are more reliant on debt finance. The fraction of bank debt of the top 0.5% of firms is 0.28 while that of the bottom 90% of firms is close to 0.5. Furthermore, the difference in the fraction with zero leverage is significant. 20% of small firms are not leveraged. The financial statistics illustrates the differences of the financial methods and conditions between small and large firms.

The firms with different sizes are heterogeneous in their responses along with business cycle. In general, small firms are more sensitive to aggregate fluctuations. Figure 1 illustrates the comparison of the mean of the sales growth rate between small and large firms across sectors over business cycle with the COMPUSTAT data. The large firms are classified as the top 2 firms measured in asset within each sector defined in NACIS-6\(^2\). The variance of the growth rate of small firms is 13.69%, nearly half larger that of large firms (9.63%). Crouzet and Mehrotra (2020) documents the similar trend by the confidential QFR data in figure 2. Yet, the trend of the change of the market share of large firms is different between crisis. For example, the second plot of figure 1 plots the evolution of the market share of large firms after 1998. It shows that, consistent with the relative lower growth rate of large firms, during the recession 2000, the market share of large firms is declining, while during the crisis of COVID, the market share of large firms is increasing. The effects of crisis are not evenly distributed across firms with different sizes, and not identically distributed across different crisis. Therefore, if we measure concentration as the market share of the large firms, it implies different crisis has different implications on market concentration. Conversely, the paper is intended to explore how does the change of concentration affect the crisis.

To conclude, the statistical facts imply that to explore the relation between market concentration and business cycle, it is both quantitatively and qualitatively important to model the large and small firms simultaneously. Quantitatively, although the product market of the United State is highly concentrated, the aggregate market share of small firms is comparable to that of the top firms. Qualitatively, the market leader and the competitive fringes are not only different in their pricing strategies, but also distinguished in their borrowing capacities. Moreover, the market concentration is evolving along with business cycle and the different crisis has different effects towards small and large firms. Therefore, to investigate the implications of market concentration on business cycle, and

\(^2\)The choice of the top 2 firms is to match the market share (around 50% in the Census 2012) of large firms defined as the top 1% firms by Crouzet and Mehrotra (2020)
to emphasize the interactions between small and large firms, we consider a stylized market structure with dynamic price competition between a dominant firm and a continuum financial constrained entrepreneurs to explore how does concentration impact the dynamics of the economy.

3 Model

To evaluate the relation between boom-bust cycles and market concentration, this section presents the model with the strategic competition between a large firm and a continuum of small firms, where the markup of the large firm is endogenously determined by the strategic competition. In order to capture the heterogeneous pricing strategies of the firms, we assume that the firms are playing a dynamic Stackelberg game. The small firms are assumed to be the price-takers and thus reacting competitively as followers. Whereas the dominant firm anticipates the reactions of competitive fringes and behave like leaders. To explore the mechanism through which the particular concentrated market structure influences business cycle, we first consider the stylized impulse shocks on technology that are biased to the leader or the followers. We compare the dynamics of the economy of the aggregate output and wealth, between the case of the Stackelberg competition and the competitive benchmark where the leader is a price-taker.

3.1 Households

We assume that there exists a representative household who supplies labor $l_t$ inelastically and maximizes the discounted utility of the consumption of the final good $c_t$

$$\max_{c_t, b_t, l_t} \sum_{t=0}^{\infty} \beta^t u(c_t),$$

subject to

$$c_t + b_t = w_t l_t + (1 + r)b_{t-1},$$

$$b_t \geq 0,$$

where $b_t$ is the risk-free bond. By $b_t \geq 0$, it is assumed that the household cannot borrow. The interest rate $r$ is assumed to be a exogenous constant, which implies that the model depicts an open economy with a fixed real rate. Note that if $\beta(1 + r) < 1$, given the assumption that the household cannot borrow, it implies that the household is hand-to-mouth at the steady state.

3.2 Firms

The production side of the economy consists two layers: the final good sector and the intermediate good sectors. The final good $y$ is produced with the a continuum of intermediate good $y_i$ according to the CES aggregator:
\[ y = \left[ \int_0^1 (\rho_i(y_i)^{\frac{\sigma-1}{\epsilon}} \, dy_i) \right]^{\frac{\epsilon}{\epsilon-1}}, \]  

where \( y_i \) is the output of the intermediate good sector \( i \) and \( \rho_i \) is exogenous and represents the sector specific productivity. The CES aggregator implies that, after normalizing the price of the final good to 1, the demand function for \( y_i \) is

\[ y_i = p_i^{\sigma} \rho_i^{\sigma-1} y_i. \]  

Within each intermediate good sector \( i \), there exists a dominant firm (leader) with some constant productivity \( z_{i,l} \) and one unit of a continuum of competitive entrepreneurs (followers) indexed by \( j \in (0, 1) \). The entrepreneur \( j \) of the sector \( i \) is endowed with some productivity \( z_{i,j} \) and produces a particular variety \( y_{i,j} \) if she chooses to be active. To keep the analytical tractability of the model, the varieties produced by the entrepreneurs within the sector \( i \) are assumed to be perfectly substitutable. The output of sector \( i \) is produced by combining the output of the leader, i.e. \( y_{i,L} \) and the aggregate output of the followers \( y_{i,F} \) according to the CES technology

\[ y_i = \left[ (\rho_{i,L}y_{i,L})^{\frac{\epsilon-1}{\epsilon}} + (\rho_{i,F}y_{i,F})^{\frac{\epsilon-1}{\epsilon}} \right]^{\frac{\epsilon}{\epsilon-1}}, \]  

\[ y_{i,F} = \int y_{i,j} \, dj. \]  

where \( \rho_{i,L} \) and \( \rho_{i,F} \) represent the agent-specific productivity.

The assumption of the imperfect substitution between the dominant firm and the competitive entrepreneurs within a sector follows the idea of Holmes and Stevens (2014), that small firms are facilitated by face-to-face contact and targeted to specialty goods, while large firms focus on standardization with mass production technology. Thereafter, the elasticity of substitution between the products of the entrepreneurs and the dominant firm should be lower than the elasticity within the entrepreneurs. In particular, we assume that the outputs of competitive entrepreneurs are perfectly substitutable. Furthermore, without the loss of generality, the elasticity of substitution \( \sigma \) across sectors is assumed to be less than the elasticity \( \epsilon \) within a sector.

The standard CES aggregator implies that the demand for the leader and the aggregate demand for the followers within the sector \( i \) take the form that

\[ y_{i,L} = \left( \frac{p_{i,L}}{p_i} \right)^{-\epsilon} \rho_i^{\epsilon-1} y_i, \]  

\[ y_{i,F} = \left( \frac{p_{i,F}}{p_i} \right)^{-\epsilon} \rho_i^{\epsilon-1} y_i, \]  

where \( \rho_{i,L} \) and \( \rho_{i,F} \) represent the agent-specific productivity.
where the price index $p_i$ equals to

$$p_i = \left[ \left( \frac{p_{i,L}}{\rho_{i,L}} \right)^{1-\epsilon} + \left( \frac{p_{i,F}}{\rho_{i,F}} \right)^{1-\epsilon} \right]^{\frac{1}{1-\epsilon}}. \quad (10)$$

### 3.2.1 Timing

To characterize the heterogeneity in pricing strategies across firm size, we assume that the large and small firms are playing a dynamic Stackelberg game over price: with the market power, the large firm anticipate the policy functions of the entrepreneurs and announce the pricing rule as a leader. Whereas observing the announcement of the large firm, the competitive small firms are price-takers. The game is dynamic therefore leaders are forward-looking. The timing of the game across all the sector $i \in (0, 1)$ is identical and shown as follows.

1. At time $t$, given cash-on-hand $m_{i,j}$, the entrepreneur $j$ in the sector $i$ draws a new productivity $z'_{i,j}$ from an i.i.d. Pareto distribution $g_i(z) = \gamma_i z^{\gamma_i - 1}$ with a Pareto parameter $\gamma_i > 1$;

2. the productivity shocks $\rho'_i, \rho'_{i,L}, \rho'_{i,F}$ of the next period are realized;

3. the leader of the sector $i$ announces the price of the next period $p'_{i,L}$;

4. taken $p'_{i,L}, p'_i$ and $p'_{i,F}$ as given, the followers choose saving $a'_{i,j}$ and output $y'_{i,j}$ for the next period.

5. at time $t + 1$, the leaders and followers produce according to the plan.

The following diagram summarizes the timeline of the game.

![Diagram of game timeline](diagram)

### 3.2.2 Followers

Now consider the entrepreneur $j$ of the sector $i$, after drawing the productivity $z_{i,j}$ of the next period, the Bellman equation of that entrepreneur can be written as

$$v_{i,j} (m_{i,j}, z_{i,j}) = \max_{y'_{i,j}, a'_{i,j}, l'_{i,j}, k'_{i,j}} \log (m_{ij} - a'_{ij}) + \beta Ev_{i,j} (m'_{i,j}, z'_{i,j}), \quad (11)$$
subject to

\[ m'_{i,j} = (1 + r) a'_{i,j} + \pi'_{i,j}, \]  
(12)

\[ \pi'_{i,j} = p'_{i,F} y'_{i,j} - w' l'_{i,j} - r k'_{i,j}, \]  
(13)

\[ y'_{i,j} \leq (z_{i,j} k'_{i,j})^{\alpha - 1} \lambda a'_{i,j}, \]  
(14)

\[ k'_{i,j} \leq \lambda a'_{i,j}. \]  
(15)

Here \( m_{i,j} \) denotes an entrepreneur’s “cash-on-hand” and \( a'_{i,j} \) represents the net wealth of the entrepreneur saving for next period. Due to financial frictions, the borrowing capacity of the entrepreneur is constrained by its own net wealth: the leverage ratio of the entrepreneur is bounded by \( \lambda \). The specific formulation of capital market imperfection favors analytical convenience and is isomorphic to the model where entrepreneurs own capital and issue debt to finance the investment as discussed in Itskhoki and Moll (2019). With \( \lambda > 1 \), the entrepreneur has to have "skin in the game": the fraction of externally financed capital investment is bounded up-to \( 1 - \frac{1}{\lambda} \). Therefore, entrepreneurs choose saving \( a'_{i,j} \) not only to smooth consumption but also to satisfies the internal finance in next period.

Lemma 1 is a straight-forward generalization of the characterization of the entrepreneurs in Itskhoki and Moll (2019).

**Lemma 1** There exists a productivity cutoff: \( z'_{i} = p' \frac{r}{\alpha} \left( \frac{w'}{1 - \alpha} \right)^{\frac{1}{\alpha} - 1}, \) such that

\[ y'_{i,j} = \begin{cases} p'_{i,F} \frac{r}{\alpha} z'_{i,j} \lambda a'_{i,j}, & z_{i,j} \geq z_{i} \\ 0, & \text{otherwise} \end{cases}, \]  
(16)

\[ \pi'_{i,j} = \begin{cases} \left( \frac{z_{i,j}}{z_{i}} - 1 \right) r \lambda a'_{i,j}, & z_{i,j} \geq z_{i} \\ 0, & \text{otherwise} \end{cases}, \]  
(17)

\[ l'_{i,j} = \begin{cases} r \frac{1 - \alpha}{\alpha} \frac{z'_{i,j}}{z_{i}} \lambda a_{i,j}, & z_{i,j} \geq z_{i} \\ 0, & \text{otherwise} \end{cases}. \]  
(18)

Furthermore, the savings of entrepreneur \( j \) is a constant fraction to cash-on-hand

\[ a'_{i,j} = \beta m_{i,j}. \]  
(19)

As shown by Lemma 1, constant return to scale together with the linear collateral constraint guarantee that the output, profit and labor demand of entrepreneur \( j \) are linear functions of savings, i.e. \( a'_{i,j} \). The linearity is the key property to keep the analytical tractability of the model. In particular, since the profit is a linear function of wealth, the rate of return on saving of the entrepreneur \( j \) is constant. Thereafter, the entrepreneur would save a constant fraction of cash-on-hand, which
The aggregate output, profit and savings of entrepreneurs in sector $i$ take the form

$$y'_{i,F} = \left( p'_{i,F} \frac{1 - \alpha}{w} \right)^{\frac{1}{\gamma} - 1} \lambda \beta m_{i,F} \int_{z_i}^{\infty} z dG_i(z), \quad (20)$$

$$\pi'_{i,F} = \frac{\alpha}{\gamma} p'_{i,F} y'_{i,F}, \quad (21)$$

$$m'_{i,F} = \beta(1 + r)m_{i,F} + \pi'_{i,F}, \quad (22)$$

where $G_i(z)$ is the cumulative probability function of $z$ following Pareto distribution.

Since the productivity shock is i.i.d., at each period, the distributions of productivity and wealth are independent. Therefore, by aggregating (16) and (19) over all entrepreneurs within sector $i$, in Lemma 2 we can derive aggregate output and the law of motion of aggregate cash-on-hand of entrepreneurs are both linear functions of the aggregate cash-on-hand of the sector $m_{i,f}$. Lemma 3 significantly simplifies the dynamics game. Due to the perfect substitution of the varieties across entrepreneurs, the demand of the leader is a function of the aggregation of the output of followers. Meanwhile, because both the aggregate output and the law of motion of cash-on-hand are only functions of the current aggregate cash-on-hand, $m_{i,f}$ could serve as a sufficient state variable in the dynamic game and we do not need to characterize the joint distribution of wealth and productivity of followers, significantly reducing the state space.

To summarize, the four key assumptions that contribute to the tractability of the model are: competitive entrepreneurs, constant return to scale, linear borrowing constraint and i.i.d. productivity shock. The assumption of competitive entrepreneurs ensures that the followers do not behave strategically. The assumptions of constant return and linear borrowing constraint together guarantee the linear policy function for the entrepreneurs. Finally the assumption of i.i.d. productivity shock reduces the state space of the dynamic game to the aggregate cash-on-hand of followers. However, it worth to mention that the only assumption required to maintain the numerically tractability of the model is the competitive entrepreneurs. Without linearity, the dynamics are numerically achievable except that one has to trace the dynamics of follower’s joint distribution of wealth and productivity.

### 3.2.3 Leaders

In each sector $i$, there exists a dominant firm whose the shares are traded in a global market. The dominant firm is assumed to be different from competitive fringes in two dimensions. First of all, compared to small firms, the dominant firm is assumed to be unconstrained. More importantly, the dominant firm in the model is assumed to behave strategically as a leader, that is, she anticipates the best response of competitive fringes and chooses the optimal pricing strategy to maximize the discounted profits. In particular, the dynamic equilibrium we are looking for is the feedback Stackelberg equilibrium. Alternatively speaking, the equilibrium is sub-game and Markov perfect. Therefore, the state space is independent of histories and only depends on the current states.
To describe the leader’s dynamic problem, it is convenient to start with the static cost minimization problem. We assume that the leader in sector $i$ produces output $y_{i,l}$ with labor $l_{i,l}$ and capital $k_{i,l}$ using a constant return to scale technology. Therefore, the cost minimization problem of the leader $i$ implies that the leader’s marginal cost of production is a constant given by

$$
\phi_i = z_{i,L}^{-\alpha} \left( \frac{r}{\alpha} \right)^{\alpha} \left( \frac{w}{1 - \alpha} \right)^{1-\alpha}.
$$

(23)

Since the leaders are traded in a global capital market and are not financially constrained, the leaders choose price $p_{i,l}$ to maximize the present value of the profits. Furthermore, since the marginal cost of the leaders is a constant, it is equivalently to characterize the pricing strategy by the markup $\kappa_i$ they charges. Subsequently, anticipating the aggregate output and law of motion of wealth of followers, the Bellman equation of the leader of sector $i$ is given by

$$
v_{i,L}(m_{i,F}; w) = \max_{\kappa_i'} \left( \kappa_i' - 1 \right) \phi_i y_{i,L}' + \frac{1}{1 + \rho} v_{i,L}(m_{i,F}'; w')
$$

(24)

subject to

$$
p_{i,L}' = \kappa_i' \phi_i',
$$

(25)

$$
y_{i,L}' = \left( \frac{p_{i,L}'}{p_i} \right)^{-\epsilon} \left( \frac{p_i'}{p_{i,L}} \right)^{-\sigma} \phi_{i,T} \left( \frac{\kappa_{i,L}}{p_{i,L}'} \right)^{1-\epsilon} y_{i,L}.
$$

(26)

$$
p_i' = \left[ \left( \frac{p_{i,L}'}{p_{i,L}} \right)^{1-\epsilon} \left( \frac{p_i'}{p_{i,F}} \right)^{1-\epsilon} \phi_{i,T} \right]^\frac{1}{1-\epsilon},
$$

(27)

$$
y_{i,F}' = \left( \frac{p_{i,F}'}{p_i} \right)^{-\epsilon} \left( \frac{p_i'}{p_{i,F}} \right)^{-\sigma} \phi_{i,T} \left( \frac{\kappa_{i,F}}{p_{i,F}'} \right)^{1-\epsilon} y_{i,F}.
$$

(28)

$$
= \left( \frac{p_{i,F}'}{w} \right)^{\frac{1}{\sigma}} \frac{1}{\alpha} \int_{z_{i,F}}^\infty z dG_i(z),
$$

(29)

$$
m_{i,F}' = \beta(1 + \rho) m_{i,F} + \frac{\alpha}{\gamma} p_{i,F}' y_{i,F}.
$$

(30)

The leader anticipates the responses of followers. First, she internalizes that by increasing her markup, it raises the price index of the sector $p_{i,L}'$, and, therefore it alters the demand and thus the equilibrium price of the followers $p_{i,F}'$, which in further decreases the demand of the leader. While dynamically, she anticipates the effect of $p_{i,L}'$ on the savings of followers. Consequently, the aggregate saving $m_{i,F}'$ influences the followers capacity to supply and thus the demand for the leader in future.

13
The FOC of the Bellman equation is

\[
y_i^t \left[ 1 + (1 - \kappa_{i,t}^{t-1}) \frac{\partial y_i^t}{\partial m_{i,F}^t} \frac{m_{i,F}^t}{p_i^t} \right] \right] + \frac{1}{1 + r} \frac{\partial v_{i,L}}{\partial m_{i,F}^t} \frac{\partial m_{i,F}^t}{\partial m_{i,F}^t} = 0,
\]

(31)

where the Envelope Theorem gives the partial derivative of value function:

\[
\frac{\partial v_{i,L}}{\partial m_{i,F}^t} = (\kappa_{i,t}^{t} - 1) \phi_t^L \frac{\partial y_i^t}{\partial m_{i,F}^t} + \frac{1}{1 + r} \frac{\partial v_{i,L}}{\partial m_{i,F}^t} \frac{\partial m_{i,F}^t}{\partial m_{i,F}^t}.
\]

(32)

The FOC of the Bellman equation consists of a static and a dynamic part. Note that by ignoring the dynamic part, one can find the standard relation between markup \( \kappa_{i,t}^{t} \) and elasticity of demand. However, in the dynamic game, different from the classical New-Keynesian or international trade models, the leader is facing a discounted elasticity of demand: the pricing strategy today not only alters the current demand but it also impacts the demand in future by influencing the savings of the followers. Denote by \( \tilde{\nu}_{i,t+k} \) the elasticity of demand in the period \( t+k \) with respective to the price \( p_i^t \) in period \( t \), and by \( \mu_{i,L,t} \) the market share of the leader, i.e. \( \mu_{i,L,t} \equiv \frac{p_{i,L,t} y_{i,L,t}}{p_i y_i} \). Lemma 4 provides the characterization of the optimal markup of the leader by combining the FOC and the Envelope Theorem iteratively.

**Lemma 3** The markup of leader is only a function of the discounted elasticity of demand \( \Upsilon_{i,t} \) such that

\[
\kappa_{i,t} = \frac{1}{1 - \Upsilon_{i,t}},
\]

(33)

where \( \Upsilon_{i,t} \) is the sum of the static elasticity \( \nu_{i,t} \) and the discounted present value of the forward-looking elasticity \( \tilde{\nu}_{i,t+k} \) given by

\[
\Upsilon_{i,t} = \nu_{i,t} + \sum_{k=1}^{\infty} \left( \frac{1}{1 + r} \right)^k \frac{\pi_{i,L,t+k}}{\pi_{i,L,t}} \nu_{i,t+k},
\]

(34)

\[
\nu_{i,t} = \epsilon - (\epsilon - \sigma) \left[ 1 + \left( \frac{1}{\mu_{i,L,t}^{t-1}} - 1 \right) \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1},
\]

(35)

\[
\tilde{\nu}_{i,t+k} = \frac{\partial y_{L,t+k}^t}{m_{L,t+k}^t} \frac{m_{L,t+k}^t}{m_{L,t+k}^t} \frac{m_{F,t+k}^t}{m_{F,t+k}^t} \frac{p_{F,}\partial p_{L,t}}{p_{F,t}} \frac{\partial p_{L,t}}{p_{L,t}}, k \geq 1.
\]

(36)

In particular, \( \nu_{i,t} \) is a decreasing function of \( \mu_{i,L,t} \) such that

\[
\lim_{\mu_{i,L,t} \to 1} \nu_{i,t} = \sigma,
\]

(37)

\[
\lim_{\mu_{i,L,t} \to 0} \nu_{i,t} = \epsilon.
\]

(38)
Lemma 3 reveals that the optimal markup still is only a function of the elasticity of demand, except that different from the standard case, the elasticity of demand of the leader is a summation of the static elasticity and the discounted present value of the forward-looking elasticity. Furthermore, the static elasticity, i.e. \( v_{i,t} \), is a function of market share of the leader, while in the standard case with CES aggregator, the elasticity of demand is a constant given by the within-sector elasticity of substitution.

Equation (34) highlights the difference between the dynamic game and standard CES models. First of all, \( v_{i,t} \) is a decreasing function of the leader’s market share and bounded between \([\sigma, \epsilon]\). Intuitively, when the market share of the leader is approaching to 1, the leader is a monopoly in the intermediate good sector \( i \). However, because the final output is CES aggregated by a continuum of intermediate good, the leader is then monopolistic competitive in the upper-layer of the economy. Thereafter the static elasticity of demand equals to the between-sector elasticity of substitution \( \sigma \). On the contrary, when the market share of the leader approaches to 0, the leader is approximately behaving monopolistic competitively within sector \( i \). Therefore the static elasticity equals to the within-sector elasticity of substitution \( \epsilon \). In equilibrium, the static elasticity of demand, as a function of aggregate wealth of followers and productivity shocks, is endogenously oscillating between that of a monopolistic competitive firm and a monopoly. In addition, the second part of equation (34) explains the channel through which the current pricing affects the future demand. The leader internalizes that the current change of price would influences the profits and the savings of followers. Moreover, the leader also internalizes the law of motion of \( m_{i,F} \), therefore the followers’ abilities to borrowing and to supplying in the every future period. Subsequently, as Lemma 4 shows, the discounted elasticity of demand would be a life-time discounted elasticity that is the summation of the static elasticity and the discounted present value of the forward-looking elasticity of demand.

### 3.3 Definition of an Equilibrium

Normalize aggregate price index \( p = 1 \), and denote by \( \omega \) the exogenous fraction of the population that are entrepreneurs. Given sequences of productivity and leverage shocks, a feedback Stackelberg equilibrium is defined by sequences of allocations and prices such that:

1. Given sequences of factor prices \( \{r, w_t\}_{t=0}^{\infty} \), households choose \( \{c_t, l_t, b_t\}_{t=0}^{\infty} \) to the maximize life-time utility in (1) subject to the budget constraint by (2).

2. For all \( i, j \in (0, 1) \), given the prices sequences \( \{p_{i,L,t}, p_{i,F,t}, p_t, r, w_t\}_{t=0}^{\infty} \), the sequences of allocations \( \{c_{i,j,t}, a_{i,j,t}, y_{i,j,t}, l_{i,j,t}, k_{i,j,t}\}_{t=0}^{\infty} \) satisfies the competitive entrepreneur’s Bellman equation (11) subject to the constraints (12)-(15).

3. Anticipating entrepreneurs’ output in (20) and savings (22), taken the sequences of aggregate states \( \{w_t, y_t\} \) as given, the sequence of markups \( \{\kappa_{i,t}\}_{t=0}^{\infty} \) satisfies the Bellman equation (24) of the market leader.
4. The final goods market, the intermediate goods market, and the labor market clear:

\[ y = \left[ \int_0^1 (\rho_i y_i)^{\frac{\sigma - 1}{\sigma}} \, di \right]^{\frac{1}{\sigma - 1}}, \]  
\( (39) \)

\[ y_i = \left[ (\rho_{i,L} y_{i,L})^{\frac{\epsilon - 1}{\epsilon}} + (\rho_{i,F} y_{i,F})^{\frac{\epsilon - 1}{\epsilon}} \right]^{\frac{1}{\epsilon - 1}}, \forall i \in (0, 1) \]  
\( (40) \)

\[ (1 - \omega)L = \omega \int \left( l_{i,L} + \int l_{i,j} \, dj \right) \, di. \]  
\( (41) \)

4 Closed-form characterizations

To analytically explore the effect of market concentration on business cycles, we characterize the evolution of the economy after productivity shocks with log-linearization. To highlight the role of the strategic behaviors of the leaders, we compare the dynamics of the economy with that of the monopolistic competitive (hence MC) benchmark. The structure of the benchmark is isomorphic to that of the model with strategic competition, except that the leaders in the benchmarks are behaving non-strategically.

The analysis emphasizes the importance of the strategic behavior of leaders. We observe two important results. First, the effect of concentration on business cycle is non-monotonic and shock-specific: conditional on how does the shock alter the market power of leaders, the endogenous change of markups might amplify or mitigate the accumulated effects of shocks. Furthermore, the direct effect of endogenous markup and the effect of it along with transition dynamics are contradictory. For the shocks increase the market power of leaders, the raised markup amplifies the impact of the shock. Yet, the higher markup dampens the decline of the wealth of the constrained entrepreneurs and, therefore, accelerates the recovery of the economy. The opposite is same for the shocks that declines the market power of leaders.

The section would proceed in the following order. First it would introduce the shocks, followed by the definition of the monopolistic competitive benchmark. Afterwards, it compares the dynamics of the economy between the benchmark with the model of strategic competition.

4.1 Formulating the shocks

We assume that economy starts at an steady state with \( \rho_{i,j,1} = 1 \), where \( i \in (0, 1) \) and \( j \in \{L, F\} \). To reveal the mechanism of the model, we impose agent-specific and unanticipated impulse productivity shocks that are symmetric across sectors.

Define by \( d \log x_t \) the deviation of \( x_t \) away from its steady state value, i.e. \( d \log x_t \equiv dx_t/x \). The system starts at the steady state. At \( t = 1 \), we assume there is an unanticipated impulse shock on leaders or on followers that is symmetric across sectors. After the period of the shock, the
productivity permanently reverts to the initial value from period $t = 2$ onward. In particular,

$$d \log \rho_{L,t} = \begin{cases} 
0, & t = 0, \\
 d \log \rho_{L,1} < 0, & t = 1, \\
0, & t \geq 2.
\end{cases}$$

or

$$d \log \rho_{F,t} = \begin{cases} 
0, & t = 0, \\
 d \log \rho_{F,1} < 0, & t = 1, \\
0, & t \geq 2.
\end{cases}$$

Note that since the shock is symmetric across sectors, I drop the subscript $i$. The parameter $\rho_{i,j,t}$ represents the productivity of the good $j \in \{L,F\}$ in the aggregation process of the intermediate good $i$. Therefore $d \log \rho_{j,t} < 0$ captures a negative demand shock on agent $j$.

The main reason that we impose the impulse shocks is that it perfectly separates the impact and the propagation of the shock with financial frictions. The economy starts at steady state, which implies that $m_{F,1} = m^*_F$. Therefore, the deviation of the output at $t = 1$ is a direct outcome of the productivity shock. Although the productivity reverts to steady state for $t \geq 2$, the effect of the shock is persistent. The shock impacts the strength of the balance sheets of followers and, therefore, their borrowing capacity. Thus the only reason that $d \log y_t \neq 0$ for $t \geq 2$ is the propagation of the shock due to financial frictions. Furthermore, by separately comparing the deviation of output during and away from the period of the shock between the benchmark model and the model with strategic competition, we can perfectly isolate the influence of market concentration on the instantaneous effect and the propagation of the shock. The analytical tractability brought by the impulse shocks helps us to interpret the dynamics of the economy in the numerical sections where we consider persistent shocks.

4.2 Monopolistic Competitive Benchmark

To reveal the effect of market concentration, we consider the following monopolistic competitive benchmark. We denote all variables of the monopolistic competitive (MC) benchmark with tilde, i.e. $\tilde{x}_t$. The main structure of the MC is consistent with the model presented in section 3. In the production side, there exists two layers, the final good and the intermediate good sectors. Yet, in the MC, the intermediate good $\tilde{y}_i$ is an aggregation of the product of a continuum of homogeneous
unconstrained firms and a continuum of constrained heterogeneous entrepreneurs:

\[ \tilde{y}_i = \left[ (\rho_i, L \tilde{y}_i, L) \frac{\eta - 1}{\eta} + (\rho_i, F \tilde{y}_i, F) \frac{\eta - 1}{\eta} \right] \frac{\eta - 1}{\eta}, \forall i \in (0, 1), \]  

(42)

\[ \tilde{y}_i, F = \int \tilde{y}_i, j d j, \]  

(43)

\[ \tilde{y}_i, L = \left( \int \tilde{y}_i, L, j, d j \right) \frac{\eta - 1}{\eta}. \]  

(44)

Note that the within-sector market structure is isomorphic to the model of strategic competition. Furthermore, the technology of unconstrained firms is homogeneous and assumed to be identical to the leaders in the model of strategic competition. Hence in the MC, the representative unconstrained firm corresponds to the leader in the model of strategic competition. Yet, the difference is that the output of the unconstrained is a CES aggregation across a continuum of homogeneous firms with the elasticity \( \eta \). In particular, we assume that \( \eta = \Upsilon^* \), where \( \Upsilon^* \) represents the steady state elasticity of demand of the leaders in the model of strategic competition. Other than that, the benchmark is assumed to be identical to the model of concentration.

Different from the strategic leaders, the unconstrained firms behave monopolistic competitively. In particular, because \( \eta = \Upsilon^* \), they charge a constant markup \( \tilde{\kappa} \) that is identical to the steady state markup charged by the strategic leader. While the markup of the strategic leader is endogenously evolving along with the transition dynamics. Moreover, with the same productivity, the representative unconstrained firm and the strategic leader have the same market share at steady state. Therefore, through the comparison to the benchmark, we answer the question that given market concentration, how does the strategic behavior of market leaders affect business cycles.

4.3 Log-linearization Analysis

In this section we characterize and explore the effect of endogenous markup using log-linearization analysis. We disaggregate the accumulated effect of the shock into the impact effect and the propagational effect, and separately evaluate the implications of endogenous markup.

Specifically, we are comparing the three deviations: \( d \log y_1, \sum_{t=2}^{\infty} d \log y_t \) and \( \sum_{t=2}^{\infty} d \log m_{F,t} \) with respective to the MC. Note that the system starts at steady state, \( d \log y_1 \) and \( \sum_{t=2}^{\infty} d \log y_t \) isolate the impact and the propagation of the shock respectively. Because the shock is assumed to be a impulse, the deviation of the output during the period of the shock is a direct outcome of the shock, while the aggregate deviation of output in the following periods is a result of the fact that the shock impacts the strength of the balance sheet of followers. Furthermore, related to the propagational effect, given that \( m_{F,t} \) is the only state variable of the economy, \( \sum_{t=2}^{\infty} d \log m_{F,t} \) represents the aggregate deviation of the system along with the transition dynamics and \( \frac{d \log m_{F,t}}{d \log m_{F}} \) characterizes the speed of convergence. By comparing the strategic model to the MC, we can isolate the influence of endogenous markup on the whole dynamics following the shock.
4.3.1 Analysis of a Myopic-Leader

We first consider the case with a myopic leader, by assuming that the leader ignores the forward-looking elasticity defined in Lemma 3, i.e. 

\[ \frac{\partial y_{L,t+k}}{\partial y_{L,t+k}} + m_{F,t+k} y_{L,t+k} \frac{\partial m_{F,t+k}}{\partial m_{F,t+k}} = 0 \text{ for all } k \geq 1. \]

Different from a forward-looking leader, the discounted elasticity \( \Upsilon_t \) of the myopic leader is static and only a function of its market share. It worth mentioning that the assumption of a myopic leader does not implies that the pricing strategy of the leader has no influence upon the dynamics of the system. The change of the markup the still affects the wealth of followers and, therefore, alters the dynamics of the economy.

With the assumption of a myopic leader, we obtain the analytical solution for the dynamics of the system. For the model with a forward-looking leader, we will provide a sufficient condition such that the effect of the strategic competition remains consistent.

In particular, for mathematical simplicity, we calibrate the productivity of the leader such that \( \mu_L = \mu_F \), which is consistent with the market share of the large firms in the United States\(^3\). Given the simplification, the steady state markup is given by

\[ \kappa = \frac{\Upsilon^*}{\Upsilon^* - 1}, \quad (45) \]

which implies that the steady state elasticity of demand of the myopic leader is

\[ \Upsilon^* = \epsilon - \frac{(\epsilon - \sigma)}{2} \frac{\epsilon + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} + \frac{\gamma}{\alpha} - 1}. \quad (46) \]

Because the MC and the model of strategic competition share the same resource allocations and prices at steady state, the first order differences of output and wealth only consist of the response of the markup charged by the strategic leaders. Define by \( \Delta x_t \) the difference in the deviation across the two models, i.e. \( \Delta x_t = \log x_t - \log \tilde{x}_t \). After log-linearizing the system we obtain that, for \( j \in \{L,F\} \)

\[ \Delta y_t = \begin{cases} \frac{\partial y}{\partial \kappa} \frac{d \log \kappa}{d \log \rho_{j,1}}, & t = 1 \\ \frac{\partial y}{\partial \kappa} \frac{d \log \kappa}{d \log m_F} \frac{d \log m_{F,t}}{d \log m_{F,t}} + \frac{\partial y}{\partial \kappa} \frac{d \log m_{F,t}}{d \log m_{F,t}} \Delta m_{F,t}, & t \geq 2. \end{cases} \]

Equation (47) reveals that endogenous markup has two effects: the direct and the transitional effects on output. The transitional effect, characterized by \( \sum_{t=2}^{\infty} \Delta y_t \), refers the effect of the endogenous markup along with transition dynamics. In particular, for the transitional effect, we can decompose two channels: wealth-markup channel and the wealth-accumulation channel, where the latter

\(^3\)We use the definition of the large firms by Crouzet and Mehrotra (2020) as the 1% firms. According to the census 2012, the mean of number of firms within each sector is 732, while the accumulated revenue share of the top 8 firms is 54.9%.
represents how does the endogenous markup influences the dynamics through altering the wealth accumulation of the followers. Lemma 4 first explore the implication of the endogenous markup in the short run (the impact effect).

**Lemma 4** Depending on how does the shock alter the market power of the dominant firm, the endogenous markup has differentiated effects in the short run. Particularly,

1. for negative shocks on followers, i.e. \( d \log \rho_F,1 < 0 \),
   \[
   \Delta y_1 (\rho_F,1) < 0,
   \]
   \[
   \Delta y_1 (\rho_L,1) > 0.
   \]

The lemma reveals that the impact effect depends on how does the shock alter the market power of the leader. In the short run, the endogenous markup amplifies the shocks to the followers, while mitigates the shocks biased to the leader. Intuitively, as shown in equation (34), the elasticity of demand of the leader is a decreasing function of her market share. Therefore, if the shock is on the followers, the market share of the leader will increase in equilibrium. Consequently, her elasticity of demand drops and, therefore, she would increase markup endogenously. Since \( \frac{\partial \log y}{\partial \log \kappa_t} < 0 \), the increase of the markup suppresses the aggregate output raising the efficiency wedge. Thereafter, compared to the MC, the aggregate output decreases by more. Conversely, the shock biased to the leader eventually results in the decrease of the markup, and thus mitigating the decline of the aggregate output.

As shown by equation (47), the transitional effect is consisted of the wealth-markup channel and the wealth-accumulation channel. We first focus on the wealth-accumulation channel. Similarly, because the steady state prices and allocations are identical across the MC and the model of strategic competition, the difference in the first order effect of the shocks on the deviations of wealth across the two models is only because of the endogenous markup. Define by \( \Delta m_{F,t} \) the difference in log-deviation of wealth, i.e. \( \Delta m_{F,t} = d \log m_{F,t} - d \log \tilde{m}_{F,t} \). By log-linearization of equation (22) around steady state, we obtain that

\[
\Delta m_{F,t} = \left( \frac{\partial \log m'_F}{\partial \log m} + \frac{\partial \log m'_F}{\partial \log \kappa} \frac{d \log \kappa}{d \log m} \right) t^{-1} \left( \frac{\partial \log m'_F}{\partial \log \rho_j} + \frac{\partial \log m'_F}{\partial \log \kappa} \frac{d \log \rho_j}{d \log \rho} \right) d \log \rho_{j,1}(48)
\]

\[
\Delta m_{F,t} = \left( \frac{\partial \log m'_F}{\partial \log m} t^{-1} \frac{d \log m'_F}{\partial \log \rho_j} \right) d \log \rho_{j,1}(49)
\]
Note that \( m_{F,t} \) is the only state variable for the economy. Therefore aggregate deviation of the system throughout the transition dynamics can be characterized by \( \sum_{t=2}^{\infty} \Delta m_{F,t} \). The higher \( \sum_{t=2}^{\infty} \Delta m_{F,t} \) implies the wealthier followers. Lemma 6 explores the effect through the wealth-accumulation channel.

**Lemma 5** If the within-sector elasticity of substitution is large enough such that

\[
\epsilon > \frac{\kappa + 1}{2} \frac{1}{1 - \alpha} + 1,
\]

(50)

depending on how does the shock alter the market power of the dominant firm, the endogenous markup has differentiated effects on the accumulation of the wealth of the followers. Particularly,

1. for negative shocks on followers, i.e. \( d\log \rho_{F,1} < 0, \forall t \geq 2 \),

\[ \Delta m_{F,t} (\rho_{F,1}) > 0, \]

and, therefore,

\[ \sum_{t=2}^{\infty} \Delta m_{F,t} (\rho_{F,1}) > 0; \]

2. for negative shocks on leaders, i.e. \( d\log \rho_{L,1} < 0, \forall t \geq 2 \),

\[ \Delta m_{F,t} (\rho_{L,1}) < 0, \]

and, therefore,

\[ \sum_{t=2}^{\infty} \Delta m_{F,t} (\rho_{L,1}) < 0. \]

Condition (50) is a sufficient condition such that \( \frac{\partial \log m_F'}{\partial \log \kappa} > 0 \) and \( \frac{\partial \log m_F'}{\partial \log \rho_L} < 0 \). Intuitively, if the elasticity of substitution between the output of followers and leaders is high enough, the raise of the markup would benefit the followers by increasing the relative demand and thus raising the profits of followers. Likewise, with the elasticity of substitution high enough, after a positive shock on leaders, more resources would be allocated away from followers, which decreases the followers’ profit and wealth.

Lemma 5 explores the influence of market concentration on the wealth of the followers. Specifically, for the shocks on the followers, the market concentration mitigates the deviation of the wealth. Intuitively, the negative shock on the followers increases the market power of the leader. So that the leader endogenously raise her markup. When the output of the leader and the followers are highly substitutable, i.e. equation (50) satisfies, the raise of the markup of the leader increases the profits of the followers. Therefore, the economy is less deviated along with the transition dynamics.
Furthermore, one can show that $|\frac{d \log m_F^t}{d \log m_F}| < |\frac{d \log m_F^t}{d \log m_F}|$. The increased markup accelerates the speed of convergence. Conversely, with the negative shocks on the leaders, the wealth of the followers is expanding in this specific case. Yet, due to the loss of market power, the leader declines the markup, which constrains the expansion of the wealth of the followers\(^4\).

Note that the transitional effect of the endogenous markup is composed by the wealth-markup channel and the wealth-accumulation channel:

$$
\Delta y_t = \frac{\partial \log y}{\partial \log \kappa} \frac{d \log \kappa}{d \log m_F} d \log m_{F,t} + \frac{\partial \log y}{\partial \log m_F} \Delta m_{F,t} \quad .
$$

Combining with lemma 5, we can show that the effect through channel works in the opposite directions.\(^5\) To be specific, suppose there exists a negative shock on the followers, i.e. $d \log \rho_{F,t} < 0$. Following lemma 5, the increased markup dampens the contraction of $m_{F,t}$ by raising followers' profits, which implies that $\Delta m_{F,t} > 0$. The stronger balance sheets implies the higher borrowing capacity and, therefore, the wealth-accumulation channel mitigates the decline on output. Yet, note that the shock on the followers means that $d \log m_{F,t} < 0$. The leader still has greater market power in the transitional process so that throughout the transition dynamics, her markup is higher than that of the representative unconstrained firm in the MC. Therefore, the wealth-markup channel amplifies the shock in the propagation. In aggregate, the transitional effect depends on the trade-off and is not analytically tractable. We leave the discussion to the quantitative part and find that the wealth-markup channel always dominates.

To summarize, by comparing the dynamics of the model of strategic competition to the monopolistic competitive benchmark, we answer the question what is the implication of the strategic competition between large and small firms on business cycles. We disaggregate the effect of the endogenous markup into the impact effect and the transitional effect. Particularly, we find that the implications of the endogenous markup are non-monotonic in the following two dimensions. First, it implies that, the effect of the strategic competition is conditional on how does the shock alter the market power of the leader. Furthermore, we find that for the transitional effect, the wealth-markup channel and the wealth-accumulation channel work in opposite direction. Given that the wealth-accumulation channel characterizes the speed of convergence, it implies that the endogenous markup has opposite effects on the decline of the output and the speed of the recovery. We will show in the quantitative analysis that, when the effect of the shock is biased to the followers, the endogenous markup amplifies the decline on output yet accelerates the speed of convergence.

\(^4\)The impulse shock on leaders here serves an extreme example to help us interpret the implication of strategic competition after more generalized shocks, that although is biased to leaders, instead of the wealth expansion in the example, the wealth of the followers also declines. The example implies that the decreased markup dampens the rebuild of the balance sheet of the followers, which decelerates the speed of convergence.

\(^5\)Lemma 5 gives the sign of $\Delta m_{F,t}$. To show that the direct effect and the transitional effect are contradictory, one has to show the sign of the elasticity $\frac{\partial \log y}{\partial \log \kappa}$ and $\frac{\partial \log y}{\partial \log m_F}$, which are given in the derivations of lemma 4.
4.3.2 Analysis of a Forward-looking Leader

In the previous section, with the assumption of a myopic leader, we derive the specific solution of the linearized system and analyze the dynamics after impulse shocks on technology. In particular, we have the explicit solution for the elasticity of markup with respective to state variables, which is intractable when the leader is forward-looking. However, we derive a sufficient condition such that the the effect through the endogenous markup channel by characterizing the sign of the elasticity of markups with respective to aggregate states.

From equations (24)-(30), we can find the Euler equation of the leader:

\[(1 - \kappa^{-1}_t)^{-1} = \upsilon_t + \frac{1}{1 + r} \frac{\pi_{L,t+1}}{\pi_{L,t}} (\hat{\upsilon}_{t+1} - \upsilon_{t+1}) + \frac{1}{1 + r} \frac{\pi_{L,t+1}}{\pi_{L,t}} (1 - \kappa^{-1}_t)^{-1}, \quad (52)\]

where \(\upsilon_{t+1}\) and \(\hat{\upsilon}_{t+1}\) are the static and forward-looking elasticity respectively at time \(t + 1\). Lemma 6 characterizes the steady state markup charged by a forward-looking leader.

**Lemma 6** The steady state elasticity of forward-looking leader is given by

\[\Upsilon = \upsilon + \frac{\hat{\upsilon}_1}{r}, \quad (53)\]

\[\upsilon = \epsilon - (\epsilon - \sigma) \left[1 + (\mu_L^{-1} - 1) \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1}, \quad (54)\]

\[\hat{\upsilon}_1 = \frac{\gamma [1 - \beta (1 + r)] (\epsilon - \sigma)^2 (1 - \mu_L) \mu_L}{(\sigma + \frac{\gamma}{\alpha} - 1 + (\epsilon - \sigma) \mu_L)^2} > 0. \quad (55)\]

It turns out that when the leader is forward-looking, same as the model of a myopic leader, the steady state discounted elasticity is a function of her market share. Furthermore, since \(\hat{\upsilon}_1 < 0\), by internalizing the effect of raising prices on the wealth accumulation of followers, the forward-looking leader has higher elasticity of demand compared to the myopic leader. Therefore, the markup charged by the forward-looking leader is lower than that of the myopic leader.

**Lemma 7** There exists \(\xi\) such that for all \(\epsilon \geq \xi\), \(\frac{d\log \kappa}{d \log m_F} < 0\), \(\frac{d\log \kappa}{d \log \mu_{F,1}} > 0\), \(\frac{d\log \kappa}{d \log \mu_{L,1}} < 0\).

Lemma 7 provides a sufficient condition such that the effect through the channel of endogenous markup remains consistent with the case where the leader is assumed to be myopic. Lemma 7 is derived from the two dimensional system of difference equations given by the Euler equation (52) and the law of motion (30). It provides a sufficient condition that if the within-sector elasticity of substitution is high enough, the leader would increase markup when its market share is increasing and decreases the markup vice-versa. Specifically, the \(\xi\) is pinned down by \(\frac{d\log \upsilon_1(\epsilon)}{d \log \mu_L} = 0\) and, therefore, for all \(\epsilon > \xi\) the one-period forward-looking elasticity is a decreasing function with respective to the market share, i.e. \(\frac{d\log \hat{\upsilon}_1(\epsilon)}{d \log \mu_L} < 0\).

Note that at steady state, the discounted present value of the forward-looking elasticity is a geometric summation of the one-period forward-looking elasticity. The sufficient condition provided
by lemma 8 could be interpreted as the condition to guarantee the discounted present value of the forward-looking elasticity is a decreasing function with respective to the market share of the leader. Intuitively, conditional on the within-sector elasticity of substitution high enough, the greater market share implies that the market leader has more monopoly power and therefore is less sensitive to the growth of its potential competitors. Besides, the static elasticity is a decreasing function of the market share of the leader. Therefore, the sufficient condition guarantees the discounted elasticity of demand for the leader declines with the increase of the leader’s market share. Thus, the channel of the endogenous markup as we discussed in the previous section remains consistent.

To conclude, we derive a sufficient condition such that the main mechanism of the endogenous markup remains consistent in the model of a forward-looking leader. Although we cannot derive the explicit solutions for the elasticity of markup with aggregate state, the sufficient condition, which requires that the within-sector elasticity high enough, guarantees the sign of the effects of endogenous markup remains consistent. In the next section, we quantify the model and compare the difference of dynamics between the myopic and the forward-looking leader with proper calibration and the standard shocks following AR(1) process.

5 Quantifying the model

In this section, we calibrate the model. We first quantify the log-analysis in section 4. We find that the endogenous markup amplifies the shocks on followers while dampens the shocks on leaders. Furthermore, because the leaders are in general more productive and less constrained, compared to the shocks biased to the leaders, the effect of the strategic competitions are more significant when the shocks are on the followers.

Given that credit crunches are isomorphic to the productivity shocks that are biased to the constrained, we compare the effect of the endogenous markup on credit crunches as in Buera and Moll (2015). We find that the effect of the credit crunch would be largely underestimated if we do not take into consideration the strategic competition. More specifically, we show that without the strategic competition, the effect of the shocks on collateral constraints is minor. Since the resources are re-allocated to the less constrained while productive firms. Yet, the effect of the resource allocation is overturned by the increasing of the markup. With the strategic competition, the economy features a greater decline in output, TFP and the demand for capital.

We generalize our analysis by considering the standard TFP shocks that homogeneously decreases the demand for the whole economy. Due to financial frictions, the small firms are more cyclically sensitive throughout the transition dynamics. Consequently, the quantitative experiment show that for the homogeneous shock, the strategic competition amplifies the aggregate decline on

\[ \xi = (\mu_L^{-1} - 1) (\sigma + \frac{\alpha}{2} - 1) - (\frac{\alpha}{2} - 1). \]

Note that \( \xi \) is a increasing function of \( \sigma \). Intuitively, when the between-sector substitution is more elastic, the intermediate firms are more inclined to substitute the output of the leader with the product of other sectors. Subsequently, the market leader is less dominated within the sector: it simultaneously faces more fierce competitions both within and between sector substitution. Therefore, it requires a higher lower bound of within-sector elasticity to guarantee that the leader is less sensitive to the wealth accumulation of followers.
output yet accelerates the recovery.

Heretofore, the paper focuses on the question that for a given level of concentration, how does the strategic competition impacts business cycles. We enrich the analysis by exploring what is the implications of the deepening of concentration, where we compares the dynamics of the economy between the models that the leaders are heterogeneous in productivity and, therefore, the economies are differentiated in the steady state concentration. The analysis features the trade-off between the effect from the change in the endogenous markup and the effect from the change in the productivity distribution. It shows that in aggregate, the concentration mitigates the homogeneous productivity shock because the leaders are more productive. Yet, the effect from the endogenous markup offsets the effect of the productivity distribution. With the more responsive markup, the positive effect from the increased productivity is reduced by a half.

5.1 Parameterization

We start by explaining the parameterization strategy of the model.

**Assigned parameters** The paper normalizes the lower bound of the Pareto distribution of the productivity of entrepreneurs by 1. Technology parameters $\rho$ across the economy are normalized to 1 at steady state. Following Buera and Moll (2015), the discount factor $\beta$ is set to 0.95, the interest rate is set as $r = 0.03$ and the borrowing capacity is set to be $\lambda = 2$. The capital share of production function is set at $\alpha = 1/3$. The within-industry and the between-industry elasticities of substitution are set at $\epsilon = 10$ and $\sigma = 1.5$ which is broadly consistent with the values of Atkeson and Burstein (2008).

**Calibrated parameters** The Pareto parameter $\gamma$ is calibrated to 1.594 to match the distribution of incomes of the firms by COMPUSTAT. It implies the steady state productivity cutoff $z$ is 2.556. Productivity of the forward-looking leaders is calibrated as $z_{i,L} = 5.589$, which implies that the steady state markup of large firms, i.e. $\frac{p_{i,L}}{z_{i,L}} \partial \Phi_{i,L} / \partial y_{i,L}^L$, is 1.298.

Table 4 summarizes the assigned and calibrated parameters together with the related moments to match.

5.2 Quantifying the Log-analysis

The log-analysis in section 4 implies that the effect of the strategic competition is non-monotonic and depends on how does the shock changes the market power of the leaders. We first quantify the log-analysis. To be more specific, we are considering the agent-biased shocks on the followers and

---

7The productivity of the myopic leader is calibrated to $\tilde{z}_{i,L} = 6.292$ to match the same revenue share (50%) of large firms in the United States. The productivity of representative unconstrained firms in benchmark is set to be same as that of the strategic leader, i.e. $z_{L} = \tilde{z}_{L}$. Together with the assumption that they charges the same markup, it implies that the steady state allocations and prices across benchmark and the strategic models are same. Therefore the difference in output highlights the effect from endogenous markup.
the leaders respectively, i.e. $d \log \rho_{F,t} < 0$ or $d \log \rho_{L,t} < 0$, that are symmetric to all the sectors in the economy. In particular, the shock recovers according to the following AR(1) process:

$$\rho_{i,t} = (1 - \delta)\rho_{i} + \delta \rho_{i,t-1}, \quad \delta \in (0,1)$$

(56)

where $\delta$ represents the persistence of the shock. To shed lights on the endogenous markup, following the same logic as the previous section, we compare the dynamic paths of the economy between the MC benchmark and the model with the strategic competition.

Figure 3 plots the evolution of resources and prices along with the biased productivity shock. Consistent with the prediction of the log-analysis, the endogenous markup amplifies the shock to the followers while mitigates the shock to the leaders. More specifically, for the shock to the followers, the market power of the leader is enhanced. Consequently, the raised markup amplifies the shock throughout the transition process while dampens the contraction of the wealth of the followers. Contrariwise, the effect of the endogenous markup is reversed after the shock on the leaders.

Furthermore, the quantitative results shows that when the shock is biased to the followers, the decline of the output in the MC is minor compared to that after the shock biased to the leaders. Hence, the effect of strategic competition is more significant when the shock is biased to the followers:

$$\sum_{t=1}^{\infty} \left| \frac{d \log y_{t}(\rho_{F,t}) - d \log \tilde{y}_{t}(\rho_{F,t})}{d \log \tilde{y}_{t}(\rho_{F,t})} \right| > \sum_{t=1}^{\infty} \left| \frac{d \log y_{t}(\rho_{L,t}) - d \log \tilde{y}_{t}(\rho_{L,t})}{d \log \tilde{y}_{t}(\rho_{L,t})} \right|.$$  \hspace{1cm} (57)

The shock biased to the followers reallocates the resources from the followers to the leaders, who are generally less constrained and more productive. Consequently, when the leader does not behave strategically, the shock is largely mitigated. Yet, the positive effect of the resource allocation is overturned by the strategic behavior of the leaders. The accumulated effect of the increased markup significantly amplifies the shock. Contrariwise, for the productivity shock that is biased to the leaders, the effect of mitigation from the endogenous markup is less significant. Because financial frictions constrains the borrowing capability and therefore, the supply of the followers.

The effect of the strategic competition on the shocks that are biased to the followers is conditional on the within-sector elasticity. When the within-sector elasticity is high, the more resources would be reallocated to the leaders and, hence, the more significant the effect of the increased markup would be. The between-sector and the within-sector elasticity of substitution are set as $\sigma = 1.5, \epsilon = 10$ to be consistent with Atkeson and Burstein (2008). In particular, the survey of Anderson and Van Wincoop (2004) shows that the within-sector elasticity is likely in the range of 5 to 10. In appendix, we re-calibrate $\epsilon = 5$ and replicate the exercises of the biased productivity shock, where the strategic competition’s effect on the shocks biased to the followers is less significant, yet still remarkably greater than that on the shocks biased to the leaders.
5.3 Credit Crunches

In this section, we explore the implication of the strategic competition on credit crunches. Buera and Moll (2015) shows that by distorting the investment decisions of the entrepreneurs, credit crunches are isomorphic to the productivity shocks on the constrained. Consequently, given that the borrowing capacity of the small firms are more constrained, the productivity shock biased to the followers shown in section 5.2 can be interpreted as a credit crunch. To compare with the credit crunches and the shocks biased to the followers, following Buera and Moll (2015), we impose a persistent shock on collateral constraints following the process given by equation (56).

Figure 4 plots the evolution of the real allocations along with the shock on collateral constraints. The credit crunch distorts the investment decisions and, therefore, lowers the aggregate productivity of the followers. Additionally, the experiment shows that the distortion is amplified by the endogenous markup. The raised markup of the leaders suppresses the equilibrium wage by decreasing labor demand, which in further lowers the productivity cutoffs of entrepreneurs. Subsequently, consistent with the case where the shock is biased to the followers, the accumulated effect of the strategic competition on credit crunches is significant. In particular, in the initial periods, the final output of the MC is even slightly increasing, compared to the significant decline in the model of strategic competition.

The increased capital in the strategic model implies the mechanism behind. In the MC, given that the shock constrains the borrowing capacity of the followers, it reallocates the resources to the more productive representative unconstrained firms and the aggregate capital demand of the economy is increasing. Consequently, the increased output of the unconstrained firms offsets the negative effect from the contraction of the collateral constraints. However, this is reversed by the strategic competition. With higher market power, the strategic leader exploits the demand by increasing markup and decreasing supply. Consistently, the aggregate demand of capital is declining in the strategic model. The accumulated effect the endogenous markup overturns the positive effect from the resource allocations and hereby, amplifies the credit crunch. The experiment emphasizes the importance of the credit crunch by revealing that, in a concentrated economy, the effect of the credit crunch on the marginal firms would be largely underestimated if we do not take the firms’ strategic behaviors into considerations.

5.4 Homogeneous productivity shocks

To explore the mechanism behind the strategic competition, we impose the impulse shocks agent-biased. In this section, we generalize our analysis by exploring the dynamics after a homogeneous shock on the productivity that is persistent and symmetric to all the sectors.

More specifically, we assume that economy stays at steady state at $t = 0$. At time $t = 1$, there is a exogenouas shock on the productivity $\rho_{i,t}$ that is symmetric across the intermediate sector. In particular, the shock recovers according to the following AR(1) process:

$$\rho_{i,t} = (1 - \delta)\rho_{i} + \delta\rho_{i,t-1}, \quad \delta \in (0, 1)$$  (58)
where $\delta$ represents the persistence of the shock. To shed lights on the endogenous markup, following the same logic as the previous section, we compare the dynamic paths of the economy between the MC benchmark and the model with the strategic competition.

The shock is homogeneous since it decreases the aggregate demand for the intermediate good sector. Yet, the effect of the shock is still biased due to financial frictions. Figure 5 plots the evolution of the economy. At the beginning, the market share of the leader is lower than the steady state value. Consistent with Ottonello and Winberry (2020), the relative marginal cost of the unconstrained firm is more elastic\(^8\). Consequently, at the beginning, the leader decreases markup which mitigates the shock. However, along with the transition dynamics, the shock is gradually transferred to the followers through financial frictions. With the contraction of the followers’ balance sheet, the leader’s market power is increasing and eventually overturns the initial negative effect of the shock. Along with the transition dynamics, the leader is increasing markup which amplifies the shock. Corresponding to the effect on the aggregate output, the effect on the wealth of the followers is reversed. Initially, the wealth of the followers declines more because of the decreased markup. Afterwards, when the shock is transferred to the followers, the increased markup accelerates the speed of convergence. As shown in the figure, the recovery of the wealth of the follower in the model of the strategic competition exceeds that in the MC.

In aggregate, the amplification dominates. Figure 6 plots the accumulated effect of endogenous markup on output and wealth respectively as a function of the initial shock on productivity. Note that the the accumulated effect of the endogenous markup is even a convex function of the shock. Also, consistent with the analysis before, the endogenous markup increases the wealth of the followers and hence accelerating the speed of convergence.

The exercise highlights the importance of the interactions between the strategic competition and the financial frictions. Even if the shock is homogeneous and initially biased to the leaders, because of financial frictions, the effect of the shock could be transferred to the followers. Consequently, although the endogenous markup mitigates the shock initially, throughout the transition dynamics, the strategic competition amplifies the shock yet accelerates the recovery.

5.5 Deepening in concentration

Heretofore, we answer the question that given a magnitude of concentration, how does the strategic competition affect business cycles. In this section, we expand our analysis to explore what is the implications of the deepening of concentration.

In particular, by separately calibrating the productivity of the leaders, we are comparing the dynamics of the system between the economies with different steady state market shares after a homogeneous productivity shock\(^9\). Consistent with Autor et al. (2020), the calibration captures the

---

\(^8\)Note that, if we ignore the change of wage, the marginal cost of the leader is constant. While the demand shock crowds out the less productive followers, which increases the aggregate productivity and lowers the marginal cost of the followers, i.e. $E(z_i | z_{-i})$. Hence the relative marginal cost of the leader is increasing and, therefore, the decline of the demand is biased to the leaders.

\(^9\)The homogeneous shock is identical to the shock described in the section 5.3. Except that the homogeneous
important feature that the more the economy is concentrated, the higher the productivities of the large firms are.

To investigate the implication of market concentration, for the given shock, we compare the aggregate deviation in output across the economies with the differentiated steady state market share of leaders, denoted by $\Delta y_{\mu L} \equiv \sum_{t=1}^{\infty} d \log y_t(\mu_L) - \sum_{t=1}^{\infty} d \log y_t(\mu^*_L)$, where $\mu^*_L$ is the baseline concentration calibrated to the data of the United State. Furthermore, we decompose $\Delta y_{\mu L}$ into

$$
\Delta y_{\mu L} = \sum d \log y_t(\mu_L) - \sum d \log y_t(\mu^*_L) + \sum d \log \tilde{y}_t(\mu_L) - \sum d \log \tilde{y}_t(\mu^*_L),
$$

(59)

or, defined by $\Delta y_{\mu L} \equiv \sum d \log \tilde{y}_t(\mu_L) - \sum d \log \tilde{y}_t(\mu^*_L)$.

The effect from the difference in endogenous markup and the difference in productivity distribution. More specifically, the responses of the markup to the shocks, i.e. $\Delta y_{\mu L}$, are differentiated across the economies with different magnitudes of concentration. Hence the first effect of the concentration comes from the heterogeneous responses of the endogenous markup: $\Delta y_{\mu L} - \Delta y_{\mu^*_L}$. Moreover, the productivity distributions are heterogeneous across the economies that are differentiated in concentration. Note that the representative unconstrained firm in the MC always charges the constant markup. We isolate the effect from productivity distribution through the difference of the deviations in output across the MC with the different steady state market share of the representative unconstrained firm.

Figure 7 plots the effect of the increasing in concentration. It turns out that the increased concentration mitigates the homogeneous productivity shock. Furthermore, by decomposition, the figure shows that the effects from the difference in the endogenous markup and the difference in productivity distribution are opposite. Note that in figure 6, we show that due to financial frictions, the followers are more sensitive to the homogeneous shock. Therefore, throughout the transition dynamics, the shock reallocates the resources from the followers to the leaders. Given that the productivity of the leader is increasing with market concentration, consequently, with the more resources re-allocated to the leaders, the raised productivity mitigates the shock.

On the contrary, the decomposition shows that the effect from the difference in the endogenous markup offsets that of the increased productivity. As plotted in figure 8, when the economy is more concentrated, the markup of the strategic leader is more sensitive to the shock. Note that

TFP shock is more standard, we apply the homogeneous shock because we are comparing the economies that are heterogeneous in the steady state market shares of the leaders and the followers. It implies that, ex-ante, the biased shock on collateral constraints or productivity have heterogeneous effects on the economies with different magnitudes of concentration.
the markup of the strategic leader is determined by \( \kappa = \frac{\Upsilon}{\Upsilon - 1} \). It implies that \( \left| \frac{d \log \kappa}{d \log \Upsilon} \right| = \kappa - 1 \): the markup is more elastic to the elasticity of demand when the degree of concentration is higher. Subsequently, when the shock alters the elasticity of demand, the strategic leader in the highly concentrated economy responds more. Consequently, when the economy is more concentrated, the endogenous effect is more significant. Due to the effect of the homogeneous shock is biased to the followers along with transition dynamics, the accumulated effect of the endogenous markup amplifies the shock and, furthermore, the amplification is more significant in the economy that is more concentrated.

In aggregate, figure 7 shows that the mitigation from the improved productivity distribution dominates. Yet, the results re-emphasize the importance of the strategic competitions: if we do not take into consideration the effect of endogenous markup, we would overestimate the implication of the increasing of concentration on business cycle by two times.

6  Policy implications

Because of financial frictions, the economy is inefficient. In the perfect market, the borrowing capacity of the entrepreneurs is not constrained, where the most productive entrepreneur gathers all the resources from the less productive firms while the latter choose to save since the market rate of the bond is higher than their rate of return if choose to be active. Therefore, Buera and Moll (2015) argued that the credit crunch is isomorphic to a TFP shock since it distorts the entrepreneurs’ investment decisions. Conversely, as discussed by Itskhoki and Moll (2019), the government could optimize the allocations of resources by subsidizing the constrained entrepreneurs. In this section, we are exploring how does the optimal subsidization is twisted by the strategic competition.

To be more specific, we are focusing on the implications of endogenous markup on the optimal permanent interest rate subsidization. In particular, we investigate the optimal policy in two scenarios. First, we explore how does the strategic competition alter the steady state optimal interest rate cut. Furthermore, by imposing shocks on the wealth of the entrepreneurs, we investigate what is the response of the optimal policy responds to the shocks and in further how does the strategic competition distorts the optimal policy responses after the shock.

6.1  The uniform interest rate subsidization

We start with the standard policy of the uniform interest rate cut that is applied to all the active firms within the economy. We assume that, financed by the lump-sum tax on households, the utilitarian government maximizes the discounted welfare of the households and entrepreneurs by subsidizing the interest rate payment of the active entrepreneurs and large firms. The government cannot directly re-allocate wealth across different individuals while it internalizes the pricing strategies of the leaders and the saving functions of each individual entrepreneurs.

Given some initial distribution \( G_0(a, z) \) of entrepreneurs, the utilitarian government chooses the
subsidy rate $\tau_r$ to maximize

$$\sum_{t=0}^{\infty} \beta^t \left[ (1 - \omega) u_h \left( c_t \right) + \omega \int u_f \left( c_f(a, z) \right) dG_t(a, z) \right],$$

(63)

subject to

$$c_{h,t} + b_{t+1} = w_t l_{h,t} + (1 + r) b_t + T_t,$$

(64)

$$T_t = r \tau_r \left( k_{L,t} + \int_z k_{j,t} dG_t(a, z) \right),$$

(65)

together with all the market clearing conditions and the policy functions provided by Lemma 1 to Lemma 4. With the subsidization, the interest rate paid by the active firms is given by

$$r^* = r (1 + \tau_r).$$

(66)

For simplicity, equation (65) implies that we assume the government is clearing its budget constraint each period.

6.1.1 The optimal interest subsidization at steady state

We start by the analysis of the optimal steady state policy. By assuming the economy starts from the steady state without policy intervention, i.e. $G_0(a, z) = G^*(a, z; 0)$, we explore what is the optimal subsidization $\tau_r$ throughout the transitions from the initial state to a new steady state, i.e. $G^*(a, z; \tau_r)$. Consistent the analysis before, to highlight the effect of endogenous markup, we compare the optimal intervention with strategic competition to the case where the leader has the identical technology yet behaves monopolistic competitively.

Figure 9 displays the optimal subsidization of the utilitarian government. The disaggregation of the welfare of entrepreneurs and households are plotted as in figure 10. The optimal interest rate implied by the two models are distinct. For the benchmark, the general interest rate cut is favored by the government. In particular, even with the negative transfer, the welfare of the households is improving with the subsidization. Yet, for the entrepreneurs, in aggregate they are worse off even if being subsidized. While the government prefers raising the interest rate in the model with strategic competitions.

We start by explaining the result of the benchmark. The interest rate subsidization has distinct implications on the unconstrained firms and the constrained firms. Since the constrained firms always borrow up-to-limit, the interest rate cut does not enhance the borrowing capacity of the constrained firms directly. If we do not take into account the effect on the equilibrium prices, the policy is isomorphic to a direct transfer from the households to the constrained firms. In particular, the marginal cost of the constrained firms is inelastic to the interest rate cut. However, for the unconstrained firms, the decrease of the interest rate distorts the their demand of capital which lowers their marginal cost. Therefore, consistent with Ottonello and Winberry (2020), the large
firms are more responsive to the interest rate cut because they are unconstrained and have a flatter marginal cost curve. It implies that the uniform interest rate cut is biased to the large firms in our model.

Moreover, since the marginal cost of the large firm is more elastic, the policy distorts the demand of the output within the intermediate good sectors and reallocates resources from the small firms to the large firms. In particular, when the elasticity of substitution within-sector is high enough\(^ {10} \), the interest rate cut could even decreases the wealth of the followers. Intuitively, the more substitutable the outputs are, the more sensitive the relative demand is to the change of the relative marginal cost. When the substitutability is high enough, the aggregate wealth of the followers is decreasing because of the decline in the demand. Consistent with the analysis, figure 10 shows that the wealth of the followers in the benchmark is declining. However, the decline of the entrepreneurs' welfare is offset by the welfare improvement of the households. With more resources reallocated to the more productive unconstrained firms, the labor demand is increasing which benefits the households. In aggregate, the economy prefers the uniform subsidy in the benchmark.

Yet, everything is overturned by the strategic competition. As shown by figure (11), since the policy is by its nature benefiting the large firms, they are raising markups, which reverses the welfare of both the entrepreneurs and the households. First, the increased markup raises the relative demand for the followers. Therefore, different from the benchmark, the wealth and the welfare of the entrepreneurs are improving along with the subsidization. However, the raised markup decreases the welfare of the households by suppressing the labor demand and, therefore, the equilibrium wage. With endogenous markup, instead of the subsidy, the government prefers the taxing on the interest rate.

We draw two main lessons from the analysis of the steady state policy. First, because the marginal cost of unconstrained firms are more elastic, the uniform interest rate cut might not benefit the targeted constrained firms. Second, the exercise emphasizes the importance of endogenous markup in the welfare analysis. We would largely underestimate the fiscal cost to implement the policy, if we do not internalize the effect of endogenous markup. More specifically, endogenous markup has differentiated implications on the welfare of the entrepreneurs and the households: (i) because of the raising markups, the followers could still benefit from the policy that is biased to the leaders; (ii) on the contrary, the raised markup largely amplifies the welfare cost of the households to implement the policy.

6.2 The biased interest rate subsidization

The analysis of the uniform interest rate cut implies that the large firms actually benefit more from the policy, because their marginal cost is more elastic to the factor prices. When the within-sector elasticity of substitution is high enough, the constrained entrepreneurs might even be worse off because the policy re-allocates resources to the unconstrained large firms. Therefore, it motivates us to consider the policy that biased to the constrained entrepreneurs.

\(^ {10} \)The lower bound of the elasticity of substitution is given by \( \xi = \frac{(\kappa+1)}{2} \frac{(2\gamma-1)}{1-\alpha} + 1. \)
To be more specific, similarly, we assume that given some initial distribution of entrepreneurs, i.e. $G_0(a, z)$, there exists an utilitarian government who maximizes the social welfare function (63). Yet, we assume that the government can only subsidize the interest rate payment of the entrepreneurs. Therefore, the government follows the budget constraint

$$T_t = r\tau_r \int k_{j,t} dG_t(a, z).$$

(67)

The other constraints remains consistent, except that the leader is not subsidized while the rent of the capital for the active followers is given by

$$r^* = r(1 + \tau_r).$$

(68)

6.2.1 The optimal steady state policy

We first investigate how does endogenous markup alters the optimal steady state policy. Similarly, we are considering the transition dynamics from the initial steady state distribution with $\tau_r = 0$, i.e. $G_0(a, z) = G^*(a, z; 0)$, to the new steady state $G(a, z; \tau_r)$ Figure 12 plots the discounted utility of the utilitarian government and the optimal biased interest rate cut. Different from the uniform interest rate subsidization, both in the benchmark and in the model of strategic competition, the optimal policy is to subsidize the entrepreneurs. Furthermore, compared to the benchmark, the optimal rate of subsidization in the model of strategic competition is much higher. Additionally, the disaggregation of the welfare plotted by figure 13 shows that endogenous markup minimizes the welfare cost to implement the policy: even if there exists the negative transfer from the households to the followers, the welfare of the households could still be improved.

By plotting the prices and allocations in the new steady state, figure 14 explains the effect of endogenous markup. Because the policy is biased to entrepreneurs, the market share of the leaders is declining. Consequently, the leaders are decreasing their markup. The declined markup mitigates the cost to implement the policy in two dimensions. First, it decreases the welfare cost to implement the policy. The decline of the markup raises the labor demand and, therefore, the equilibrium wage, which minimizes the welfare cost of the households. In particular, even with the negative net transfers, the welfare of households could still be improved through the increase of the wage. Second, the declined markup offsets the negative effect from the resources allocations. The biased subsidization has the negative effect on the aggregate productivity since it reallocating resources from the more productive leaders to the less productive followers. Yet, the declined markup offsets the negative effect from the resource allocations.

To conclude, compared to the benchmark, endogenous markup mitigates the welfare cost of the biased subsidization, suggesting a more aggressive subsidization to the entrepreneurs. Furthermore, compared to the uniform interest rate cut, the economy is favoring the biased policy. In particular, the welfare improvement provided by the biased policy is 3 times higher than that given by the uniform subsidization.
6.2.2 The optimal stabilization policy

Deviating from the steady state policy, in this section, we investigate how does the concentration distorts the optimal response of the policy to the initial shock on the wealth of the followers. Figure 15 compares the response of the optimal policy to the benchmark. It turns out in both cases, after the negative shock on the entrepreneurs, the optimal response of the utilitarian government is to raise the subsidization. Define by $\frac{\tau_r(x_0) - \tau_r^*}{\tau_r^*}$ the optimal policy response after the initial shocks $x_0$. The figure shows that the optimal subsidization in the model with strategic is less sensitive to the shocks compared to the benchmark, i.e. $\frac{\tau_r^*(x_0) - \tau_r^*(1)}{\tau_r^*(1)} < \frac{\tilde{\tau}_r^*(x_0) - \tilde{\tau}_r^*(1)}{\tilde{\tau}_r^*(1)}$, where $\tau_r^*$ represents the optimal rate of subsidy and $x_0 < 1$ is the initial shock on wealth.

In further, by the disaggregation of the social welfare, figure 16 reveals that the change of the welfare of the entrepreneurs contributes to the insensitivity in the policy response. Compared to the benchmark, it features a minor difference in the welfare improvement of the economy with the initial shock, compared to the economy starting from the steady state, i.e., for $x_0 < 1$,

$$
\frac{\Delta U^e(\tau_r;x_0)}{U^e_0(x_0)} - \frac{\Delta U^e(\tau_r;1)}{U^e_0(1)} < \frac{\Delta \tilde{U}^e(\tau_r;x_0)}{\tilde{U}^e_0(x_0)} - \frac{\Delta \tilde{U}^e(\tau_r;1)}{\tilde{U}^e_0(1)},
$$

where $U_0$ denotes the welfare of the entrepreneurs with $\tau_r = 0$. Given the less significant welfare improvement on entrepreneurs, the optimal policy intervention responses by less.

Figure 17 explains how does endogenous markup distorts the policy response. Note that the markup of the strategic leader is given by $\kappa = \frac{\Upsilon}{\Upsilon - 1}$. It implies that $\left| \frac{d \log \kappa}{d \log \Upsilon} \right| = \kappa - 1$: the elasticity between the markup and the elasticity of demand is a increasing function in the markup. Because of the negative wealth shock on the followers, the market power and the markup of the leader is higher, which implies that her markup is more elastic to her elasticity of demand compared to that at steady state. When the government subsidizes the entrepreneurs, it relatively decreases the market power, and thus, the elasticity of the demand of the leader. With higher elastic markup, the leader declines the markup by more, compared to the steady state. Consistent with the analysis figure 17 plots the reaction of markup to the subsidy rate at the first period of the shock. Compared to the steady state, with the negative shock on followers, the leader’s markup reacts by more, while in the benchmark, the markup is constant. Consequently, the lowering markup distorts the profits of the entrepreneurs by more, which constrains the effect of the policy invention.

To summarize, by evaluating the optimal interest rate subsidization, we draw three main findings. First, the uniform interest rate subsidy is by its nature biased to the large firms, since they are less constrained so that their marginal cost is more elastic to the factor prices. Consequently, the increasing in markup distorts the uniform intervention by depressing the equilibrium wage and raising the welfare cost. Second, the distortion of the welfare cost suggests that the economy is preferring the more detailed and agent-biased policy. The biased policy not only direct improves wealth of the constrained firms, but also minimizes the cost of implementation by lowering the markup of the leaders and increasing the equilibrium wage. Finally, endogenous markup diminishes
the subsidization to the entrepreneurs during the crisis, suggesting that the government should be more conservative in the interest rate cut to smooth the shocks on the entrepreneurs.

7 Empirical studies

The log-linear analysis and the numerical experiments provide the following two main implications that we empirically test in this section: given a magnitude of concentration, the model implies that

1. in the short run, the shock is amplified when it increases the market share of the leader, while it is mitigated if decreases the market share of the leader;

2. in the long run, the increased market share of the leader accelerates the recovery by raising the profits of the followers, while the decreased market share of the leader decelerates speed of convergence by suppressing the profits of the followers.

To conclude, we test the direct effect and the transitional effect shown in lemma 4 and lemma 5 separately.

7.1 Data sources and measurement

This section summarizes the data sources and measurements of the empirical studies.

7.1.1 Data sources

To grasp a sketch of the dynamics of business cycles, the empirical analysis draws on the balance sheet reports of North-America public-traded firms by Compustat for the years 1980-2018, which includes the historical data of annual fundamentals for all traded firms across the economy. We first introduce our definitions of the sectors and the large firms.

Our analysis based on the assumption that the within-sector outputs are highly substitutable, which implies the definition of the sector should be narrow enough. Therefore, we define he sector in six-digit North American Industry Classification System (NAICS) level which covers more than 1200 different sectors and is the finest available definition provided by the Compustat. Furthermore, the median number of firms within the sector by the Census 2012 is 328. Yet, the Compustat covers much less firms than the Census. To distinguish the large firms from the small firms with the Compustat, and to trace the cyclicality of the market share of large firms around business cycles, the exercise excludes the sectors with number of firms less than 10. The refined sample includes 312 sectors. The median number of firms within each sector is 32.

The analysis requires a time-consistent definition of large and small firms. We define the large firms as the top-2 firms within each sector measured by total asset. On average, the defined large firms take up 54% of market share within each sector, which is in general consistent with the market share of large firms in US\textsuperscript{11}. The other firms are defined as small firms.

\textsuperscript{11}Following Crouzet and Mehrotra (2020), the large firms are defined to be 1% in assets. According to the Census, the aggregate market share of the top 1% firms is 54.9\%.
7.1.2 Measurement

The effect of endogenous markup depends on how does the shock locally changes the market share of the leaders. Therefore, a crucial variable connecting empirical works and the model is the measure of the change of market share. Denote by $s_{i,j,t}^{12}$ as the annual sales of the firm with $j$th amount of total asset in the sector $i$ during the year $t$, the market share of the leaders and the change of the market share are then defined as

$$
\mu_{i,L,t} = \frac{\sum_{j=1}^{2} s_{i,j,t}}{\sum_{j=1}^{N_t} s_{i,j,t}},
$$

(70)

$$
\Delta \mu_{i,L,t} = \mu_{i,L,t} - \mu_{i,L,t-1},
$$

(71)

where by $N_t$ we denote the total number of firms within the sector $i$.

It worth to mention that since the Compustat only contains the balance sheet of the active firms, the market share measured might not the actual leaders of the sector: chances are that the market leader is not public traded. More importantly, the change of the market share we defined are susceptible to the market operation of the leaders including while not limited to, list and delist, or merger and acquisition. Therefore, to reduce the error of the measurement, the sample precludes the sectors with different leaderships for consecutive years. By excluding the sectors changing the leaderships, the measurement precludes the influence of market operations on the change of the market share.

To capture how does the local change of leaders’ market share alters business cycles, another key variable to trace is the growth rate of the output. Consistent with the measurement of market share, the growth rate of the sector $i$ at year $t$ is measured by the log difference of the aggregate sales by

$$
g_{i,t} = \ln s_{i,t} - \ln s_{i,t-1},
$$

(72)

$$
s_{i,t} = \sum_{j=1}^{N_{i,t}} s_{i,j,t},
$$

(73)

where denote by $N_{i,t}$ the number of the firms of the sector $i$ at year $t$.

Finally, the sales, together with all the other subsequent control variables, are normalized to the real values of the year 1980 by Producer Price Index (PPI) of all commodities. The PPI is modified to annual value by linear average.

\footnote{The reports of balance sheet provided by Compustat are based on firms’ fiscal years. All the values are the linearly adjusted to calendar years according to the fiscal-year of the firm.}
7.2 Empirical test of the short-run effect

In this section we test the short-run implication of endogenous markup on business cycles. The model implies that the influence of endogenous markup depends on how the shock alters the market share of the leaders. Specifically, since the elasticity of demand of the strategic leader is decreasing with respect to the leader’s market share, the leader would charge a higher markup when her market share is increasing, which raises the efficiency wedge and amplifies the shock in the short run. Conversely, if the market share of the leader declines after the shocks, the decreased markup mitigates the contraction of the economy. Therefore, the model implies a negative relationship between the difference in the market share of the leader \( \Delta \mu_{i,t} \) and the demeaned growth rate of the sector \( \tilde{g}_{i,t} \), which are given by

\[
\begin{align*}
\tilde{g}_{i,t} &= g_{i,t} - \bar{g}_t, \\
\bar{g}_t &= \frac{1}{M_t} \sum_{i=1}^{M_t} g_{i,t},
\end{align*}
\]

where denote by \( M_t \) the number of the sectors of the year \( t \).

Figure 18 plots the relationship between \( \Delta \mu_{i,L,t} \) and \( \tilde{g}_{i,t} \) over the periods 1980-2018. Many outliers though it has, in generally the plot still reveals a negative relationship. By precluding the data with different leaderships for the consecutive two years, the sample excludes the effect from the list or delist of large firms. Yet, the sample does not exclude the effects of the list or delist of small firms, which would mechanically imply the negative relationship. Considering the output of the existing firms holds exactly same as the previous year, the new listed small firms mechanically increases the aggregate output while decreases the market share of leaders. Thereafter, further detailed analysis is required to control the size of the sector.

We estimate the model predicting sector growth rate of the form

\[
\tilde{g}_{i,t} = \delta_{i,t} + \beta_0 \times \Delta \mu_{i,L,t} + \beta_2 \times \mu_{i,L} + \beta_3 \times X_{i,t} + e_{i,t},
\]

where the dependent variable is the demeaned growth rate of the sector \( i \) at time \( t \). \( x_{i,L} \) is the mean of the market share of the sector \( i \). Note that our analysis of the effect of endogenous markup is based on the fixed magnitude of concentration. Therefore, we control the concentration with the mean of market share of each sector. \( X_{i,t} \) is the vectors of controls related to the size effect and standard error \( e_{i,t} \) are clustered at the sector level. Since the dependent variable is annually demeaned, the model does not contain the time fixed effect. The model is separately estimated by sub-samples of two time periods and by pooling all available data across 1980-2018.

Table 5 confirms that for all three samples, there exists a robust negative relationship between the market share of leaders and the demeaned growth rate of the sector. The positive coefficient in front of the difference in number of firms confirms the mechanical relation between the sector growth rate and the number of small firms. By controlling the difference in number of firms, the regression excludes the influence of the list or delist behaviors of small firms and still renders a
robust negative relation between the growth rate of the sector and the change of the market share of the leaders. The negative coefficient of total asset implies the decreasing return. Finally, the sub-regression of the period 1980-2000 and 2001-2020 confirms our analysis about the effect of the deepening of concentration. Our analysis implies that the markup responses more when the market leader has higher steady state market share. The weighted mean of leaders’ market share in the period of 2001-2018 is 54.82%, higher than that of in the period 1980-2000 (43.13%). It predicts that the growth rate should response more during the period 2001-2018 to the change of leaders’ market share. The regression of the two sub-group confirms the implications on the deepening of concentration.

7.3 Empirical test of the long-run effect

In this section we test the transitional effect of endogenous markup. The model predicts that, given a magnitude of concentration, if the shock increases the market share of leaders, the raised markup increasing the profits of followers, which smooths the spread of the shock. Vice-versa for the shock that decreases the market share of leaders. We test the prediction from the two dimensions, across-crisis and within-crisis.

First of all, between different crisis, for the crisis that is biased to leaders (characterized by the local decrease of the market share of leaders), the model implies that the crisis is more persistent and has prolonged recovery process. Contrariwise, the recovery process of crisis is less persistent when the market power of the leader is enhanced during the crisis.

Figure 19 plots the recent three main crisis: the 2001 recession, the financial crisis and the crisis of the COVID-19. Measured with the COMPUSTAT data, the three crisis are different in change of dominant firms’ market share. During the 2001 recession, the market share of leader declines, while in the crisis of COVID-19, there exists a significant trend of increase in concentration. The financial crisis is measured in between where initially, the market share of the leader is below the trend, but is constantly increasing during the crisis. The trend of market share measured by COMPUSTAT is in general consistent with the measured change documented by Crouzet and Mehrotra (2020) in figure 2 with the confidential QFR data: the market concentration increased during the financial crisis while decreased in the recession 2001. Consistent with the model’s prediction, with the increase of the market share, the real GDP and sales after the crisis of COVID is bouncing back very quickly compared to the other two crisis. Furthermore, compared to the financial crisis, although the recession 2001 is interpreted as a shorter crisis, it takes roughly similar period of time for the full recovery. In particular, the net income of the followers declines even further and takes more time to recover. The evolution of the sales of the followers is consistent with that of liability. Although we do not observe the vast bankruptcy and the short of liquidity as the financial crisis, the liability of the followers during the recession 2001 declines by a lot, compared to the minor change of that of the leaders. The trend of the liability is consistent with the transitional effect of endogenous markup. As the shock is biased to leaders, the declined markup suppresses the rebuilding of the balance sheet of followers which constrains their borrowing capacities.
In further, we complement our analysis by test the relation between the change of the leaders' market share and the future growth of equity and income of followers within the period of financial crisis.

Figure 20 plots the relation between the future demeaned growth rate of the followers $i$ and the current change of market share of the leaders. The first and the second row confirm the predictions of the transitional effect, by showing the positive relation between the current change of the leaders' market share and the followers' growth rate of equity and income in next period. In further, the regression shown in table 6 the positive relation is statistically significant. Except the standard controls as in previous sections, the regression additionally controls a term of lags to rule out the possibility that the equity and income of followers are mean-reverting. With the p-values around 5%, the positive relation plotted in figure 20 cannot be rejected. Finally, note the the table shows that the relation between the change of market share and the future growth of the sector is insignificant, which is also consistent with our analysis. Note that the transitional effect and the direct effect are contradictory. If the shock is biased to the leader, the raised markup although mitigates the spread of the shock by raising the profits of the followers, the direct effect of raising markup increases the efficiency wedge and amplifies the shock. Therefore, the relation between the future growth rate and the change of the market share depends on the trade-off. Consistent with the prediction, despite the significantly negative relation between $\Delta m_{i,L,t}$ and $\tilde{g}_{i,t}$ in the short run empirical analysis, the relation between $\Delta m_{i,L,t}$ and the future growth rate $\tilde{g}_{i,t}$ is insignificant.

8 Conclusion

The paper analyzes the interactions between market concentration and business cycle, by focusing on the particular market structure with a dominant firm and continuum competitive constrained entrepreneurs. To shed light on the implications of concentrations, we compare the dynamics of the model to the isomorphic benchmark, where the dominant firms are assumed to be monopolistic competitive and therefore all the firms are charging constant markups. We disaggregate the accumulated effect of shocks into the instantaneous effect and the propagational effects, so as to separately evaluate the implications of the concentration through the two effects. We in further pin down two channels, the direct and the indirect channel, through which the market concentration affects the two effects of the shocks. The direct channel is related to the large firms have greater productivities, while the indirect channel refers to the endogenous markup of the market leaders. The closed form analysis together with the numerical experiments show that the relation between the market concentration and the economic business cycle is mainly driven by the indirect channel and therefore conditional on how does the shock alter the market power of the dominant firms. For the shock that increases the market share of the leader, the leader endogenously raises the markup, which amplifies the shock in short run but smooth the shock in the propagation process by increasing the relative demand for the entrepreneurs. Reversely, for the shock decreases the market share of the leader, the intuition remains same and the implication of the market concentration is then
reversed. Quantitative results show that in aggregate, the effect in short run always dominates.

Appendices

A Proofs

Proof of Lemma 1  Given the prices, the constant return to scale implies that the marginal cost of the entrepreneur $j$ is a weakly increasing function of $y_{i,j}$. Therefore, the output, the labor demand and the profit are corner solutions and linear with respective to $a'_{i,j}$.

Proof of Lemma 2  Lemma 1 implies that the entrepreneur’s rate of return on saving is a constant given by

$$ r_{i,j} = (1 + r) + \max \left\{ 0, \left( \frac{z_{i,j}}{z_i} - 1 \right) r \lambda \right\}. \quad (77) $$

Note that $p'_{i,t}$, $p'_i$, $p'$ and productivity $z'_{i,j}$ are revealed before the saving decision. Therefore, the entrepreneur $j$ has no precautionary saving motive. Together with the logarithmic utility function, the saving of entrepreneur is a constant fraction $\beta$ of $m_{i,j}$.

Proof of Lemma 3  Since productivity shocks on $z_{i,j}$ is i.i.d., the distributions of wealth and productivity are independent. Therefore, $y_{i,f}$ and $m'_{i,f}$ are linear functions with respective to $m_{i,f}$, which implies that $m_{i,f}$ serves as the sufficient state variable of the model.

Proof of Lemma 4  The FOC of the Bellman equation of leaders (24) takes the form that

$$ y_{i,l,t} + \frac{(\kappa_i - 1) \phi_{i,l,y_{i,l,t}}}{p_{i,l,t}} \frac{\partial y_{i,l,t}}{\partial p_{i,l,t}} + \frac{1}{1 + r} \frac{\partial v_l}{\partial m_{i,f,t+1}} \frac{\partial m_{i,f,t+1}}{\partial p_{i,l,t}} \frac{\partial p_{i,l,t}}{\partial p_{i,l,t}} = 0. \quad (78) $$

By the envelope theorem, the bellman equation of leaders implies

$$ \frac{dv_l}{dm_{i,f,t}} = (\kappa_i - 1) \phi_{i,l,y_{i,l,t}} \frac{\partial y_{i,l,t}}{\partial m_{i,f,t}} + \frac{1}{1 + r} \frac{dv_l}{dm_{i,f,t+1}} \frac{\partial m_{i,f,t+1}}{\partial m_{i,f,t}}. \quad (79) $$

Combining the FOC and the envelope theorem recursively, it gives that

$$ \kappa_t = - (\kappa_t - 1) \frac{\partial y_{i,l,t}}{p_{i,l,t}} \frac{\partial p_{i,t}}{p_{i,l,t}} \frac{\partial y_{i,l,t+1}}{\partial p_{i,t}} \frac{\partial p_{i,t}}{p_{i,l,t}} \frac{\partial y_{i,l,t+1}}{\partial p_{i,t}} \frac{\partial p_{i,t}}{p_{i,l,t}} \ldots. \quad (80) $$

$$ \ldots \quad (83) $$
Alternatively,

\[ \kappa_t = \frac{1}{1 - \Upsilon_t^{-1}}, \]  

(84)

where

\[ \Upsilon_t = \frac{\partial y_{i,t,t}}{\partial p_{i,t,t}} + \sum_{t=k}^{\infty} \left( \frac{1}{1 + r} \right)^k \pi_{i,t} \frac{\partial y_{i,t+k}}{\partial p_{i,t+k}}. \]  

(85)

For static elasticity \( \upsilon_{i,t} \), taken \( p \) and \( y \) as given, differentiation of equation (26), we have

\[ \frac{d y_{i,t}}{y_{i,t}} = -\epsilon \frac{d p_{i,t}}{p_{i,t}} + (\epsilon - \sigma) \frac{d p_{i,t}}{p_{i,t}}, \]  

(86)

where \( \frac{d p_{i,t}}{p_{i,t}} \) is given by the differentiation of equation (27) that

\[ \frac{d p_{i,t}}{p_{i,t}} = \mu_{i,t} \frac{d p_{i,t}}{p_{i,t}} + (1 - \mu_{i,t}) \frac{d p_{i,t}}{p_{i,t}}. \]  

(87)

Taken \( p \) and \( y \) as given, the differentiation of the equation (28) and (29) give that

\[ \frac{d p_{i,t}}{p_{i,t}} = \frac{\epsilon - \sigma}{\epsilon + \frac{\gamma}{\alpha} - 1} \frac{d p_{i,t}}{p_{i,t}}. \]  

(88)

Substitute into \( \frac{d y_{i,t}}{y_{i,t}} \), we can derive that

\[ \upsilon_{i,t} = -\epsilon + (\epsilon - \sigma) \left[ 1 + \left( \mu_{i,t}^{-1} - 1 \right) \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1}. \]  

(89)

**Proof of Lemma 5** By the definition of leaders’ markup, \( \frac{d p_{i,t}}{p_i} \) is given by

\[ \frac{d p_{i,t}}{p_i} = \frac{d \kappa_t}{\kappa} + (1 - \alpha) \frac{d w_t}{w}. \]  

(90)

In the symmetric equilibrium, \( \frac{d p}{p} = 0 \). Therefore

\[ \frac{d p_{f,t}}{p_f} = -\frac{d \kappa_t}{\kappa} - (1 - \alpha) \frac{d w_t}{w} + \frac{d \rho_{l,t}}{\rho_l} + \frac{d \rho_{f,t}}{\rho_f}. \]  

(91)

The aggregate labor demands for followers and leaders are

\[ l_{f,t} = \left( p_{f,t} \frac{1 - \alpha}{w} \right)^{\frac{1}{\alpha}} \lambda \beta m_{f,t} \frac{\gamma}{\gamma - 1} z_t^{1-\gamma}, \]  

(92)

\[ l_{l,t} = y_{l,t} z_t^{-\alpha} \left( \frac{1 - \alpha}{w_t} \right)^{\frac{1}{\alpha}} \]  

(93)
respectively. Therefore, the log-linearization implies that

\[
\begin{align*}
\frac{dl_{f,t}}{f_l} &= \frac{\gamma}{\alpha} \frac{dp_{f,t}}{p_f} - \left[ \frac{\gamma}{\alpha} (1 - \alpha) + 1 \right] \frac{dw_t}{w} + \frac{dm_{f,t}}{m_f}, \\
\frac{dl_{l,t}}{l_l} &= \frac{dy_{l,t}}{y_l} - \frac{\alpha}{w} dw_t.
\end{align*}
\] (94) (95)

Note that

\[
\frac{lf_{l}}{l_l} = \frac{p_{l}y_{l}}{p_fy_l} \left[ \frac{p_l}{z_l^{-\alpha} \left( \frac{w}{1-\alpha} \right)^{1-\alpha} \left( \frac{\gamma}{\alpha} \right)^{\alpha}} \right] = \kappa,
\] (96) (97)

substitute into labor market clearing condition, we can find that

\[
\left[ \kappa \left( \frac{\gamma}{\alpha} - \gamma + 1 \right) + \alpha \right] \frac{dw_t}{w} = \frac{dy_{l,t}}{y_l} + \frac{\gamma}{\alpha} \frac{dp_{f,t}}{p_f} + \kappa \frac{dm_{f,t}}{m_f}.
\] (98)

Log-linearization of the supply and the demand for followers, the output can be written as prices and states by

\[
\frac{dy_{l,t}}{y_l} = -\left( \frac{\gamma}{\alpha} + \epsilon - 1 \right) \frac{d\kappa_t}{\kappa} - \left[ \left( \frac{\gamma}{\alpha} + \epsilon - 1 \right) (1 - \alpha) + \left( \frac{\gamma}{\alpha} - \gamma \right) \right] \frac{dw_t}{w} + \frac{dm_{f,t}}{m_f} + \frac{\gamma}{\alpha} \frac{dp_{f,t}}{p_l} + \frac{\gamma}{\alpha} \frac{dp_{f,t}}{p_f}.
\] (99) (100)

By linearization of the demand for leaders, the output of leaders takes the form that

\[
\frac{dy_{l,t}}{y_l} = -\epsilon \frac{dp_{l,t}}{p_l} + (\epsilon - 1) \frac{dp_{l,t}}{p_l} + \frac{dy_{l,t}}{y_l}.
\] (101)

Substitute \( \frac{dy_{l,t}}{y_l} \) and \( \frac{dp_{f,t}}{p_f} \) into the labor market clearing condition, the wage can be written as functions of markups and aggregate states by

\[
\frac{dw_t}{w} = -\frac{(1 + \kappa) \frac{\gamma}{\alpha} + 2\epsilon - 1}{2 \left( 1 + \kappa \right) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 \left( 1 - \alpha \right) (\epsilon - 1)} \frac{d\kappa_t}{\kappa} \\
+ \frac{1 + \kappa}{2 \left( 1 + \kappa \right) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 \left( 1 - \alpha \right) (\epsilon - 1)} \frac{dm_{f,t}}{m_f} \\
+ \frac{\epsilon}{2 \left( 1 + \kappa \right) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 \left( 1 - \alpha \right) (\epsilon - 1)} \frac{dp_{l,t}}{p_l} \\
+ \frac{1 + \kappa}{2 \left( 1 + \kappa \right) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 \left( 1 - \alpha \right) (\epsilon - 1)} \frac{dp_{f,t}}{p_f}.
\] (102) (103) (104) (105)
Substitute \( \frac{w}{w} \) into \( \frac{w}{y} \), the deviation of the output as a function of markups and aggregate states is then given by

\[
\frac{dy_t}{y} = \frac{1 + \kappa + (1 - \kappa) (1 - \alpha) (\epsilon - 1)}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 (1 - \alpha) (\epsilon - 1)} \frac{dm_{f,t}}{m_f} + \frac{\epsilon (\kappa - 1) (1 - \alpha) \frac{\gamma}{\alpha} + \kappa (1 + \kappa) + (\epsilon - 1) (\kappa + \alpha) \text{d}k_t}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 (1 - \alpha) (\epsilon - 1)} \frac{\text{d}k_t}{\kappa} + \frac{(\gamma + \epsilon - 1) (\kappa + 1) + (\kappa - 1) (\epsilon - 1) (1 - \alpha) \frac{\gamma}{\alpha}}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 (1 - \alpha) (\epsilon - 1)} \frac{\text{d}p_{t,t}}{\rho_t} + \frac{\gamma}{\alpha} [1 + (1 - \kappa) (1 - \alpha) (\epsilon - 1)] \frac{\text{d}p_{f,t}}{\rho_f}. \tag{106}
\]

For the myopic leader, the compound elasticity \( \Upsilon_t \) is

\[
\Upsilon_t = \epsilon - (\epsilon - \sigma) \left[ 1 + \left( \mu_{l,t}^{-1} - 1 \right) \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1}, \tag{110}
\]

where

\[
\mu_{l,t} = \frac{p_{l,t}}{p_{l,t} + p_{f,t} \tilde{y}_{l,t}} \tag{111}
\]

\[
= \left( \frac{p_{l,t}}{p_{l,t} \rho_{l,t}} \right)^{1-\epsilon} \rho_{t}^{\epsilon-1} \tag{112}
\]

is a function of \( \rho_t, \kappa_t \) and \( m_{f,t} \). By applying implicit function theorem to \( \kappa_t = (1 - \Upsilon_t^{-1})^{-1} \) and log-linearization around steady state, we have

\[
\frac{d\kappa_t}{\kappa} = \frac{d\log \kappa}{\log \Upsilon} \frac{d\mu_{l,t}}{\mu_t}, \tag{113}
\]

where \( \frac{d\log \kappa}{d\log \Upsilon} \) and \( \frac{d\log \Upsilon}{d\log \mu_t} \) are steady state constants given by

\[
\frac{d\log \kappa_t}{d\log \Upsilon_t} = - \frac{\Upsilon^{-1}}{1 - \Upsilon^{-1}} \tag{114}
\]

\[
\frac{d\log \Upsilon_t}{d\log \mu_{l,t}} = \frac{-(\epsilon - \sigma) \left[ 1 + \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1} \frac{2 \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1}}{1 + \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1}}}{\epsilon - (\epsilon - \sigma) \left[ 1 + \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1} \right]^{-1} \frac{2 \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1}}{1 + \frac{\sigma + \frac{\gamma}{\alpha} - 1}{\epsilon + \frac{\gamma}{\alpha} - 1}}}. \tag{115}
\]

Since in the symmetric equilibrium \( dp_t = 0 \),

\[
\frac{d\mu_{l,t}}{\mu_t} = (1 - \epsilon) \frac{dp_{l,t}}{p_t} - (1 - \epsilon) \frac{dp_{l,t}}{p_t}, \tag{116}
\]

\[
= (1 - \epsilon) \frac{d\kappa_t}{\kappa} + (1 - \alpha) \frac{dw_t}{w} - (1 - \epsilon) \frac{dp_{f,t}}{p_t}. \tag{117}
\]
Substitute $\frac{dm_{t}}{w}$ into $\frac{dp_{t}}{\mu_{t}}$, we can find that the leaders' market share as a function of markups and aggregate states by

$$\frac{d\mu_{t,t}}{\mu_{t}} = \frac{(1 - \epsilon) \left[ (1 - \alpha (1 + \kappa) \gamma \alpha + \kappa + \alpha \right]}{2(1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1) \kappa} \frac{d\kappa_{t}}{\kappa}$$

Then substitute $\frac{dp_{t,t}}{\mu_{t}}$ into equation (113), we can pin down the $\kappa$ as aggregate states by

$$\left[ 1 + \frac{d \log \kappa \ d \log \Upsilon}{d \log \mu_{t} \ d \log \mu_{t}} \frac{(1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)}{2 (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)} \right] \frac{d\kappa_{t}}{\kappa}$$

Therefore, the elasticities in the definition of $\Delta y_{1}^{1}$ and $\Delta y_{1}^{2}$ related to the direct effect and the indirect effect are

$$\frac{\partial \log y}{\partial \log \rho_{f}} = \frac{\gamma}{\alpha} [1 + \kappa + (1 - \kappa) (1 - \alpha) (\epsilon - 1)]$$

$$\frac{\partial \log y}{\partial \log \rho_{l}} = \frac{\gamma}{\alpha} [2(1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 (1 - \alpha) (\epsilon - 1)]$$

$$\frac{\partial \log y}{\partial \log \kappa} = \frac{\epsilon (\kappa - 1) (1 - \alpha) \frac{\gamma}{\alpha} + \gamma (1 + \kappa) + (\epsilon - 1) (\kappa + \alpha)]}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + 1 + \kappa + 2 (1 - \alpha) (\epsilon - 1)}$$

Note that for the competitive benchmark, $\frac{\partial \log y}{\partial \log \rho_{f}}$ and $\frac{\partial \log y}{\partial \log \rho_{l}}$ are homomorphic to that of strategic leaders, except that the steady state $\kappa$ is substitute by the $\bar{\kappa}$ of the competitive benchmark with $\kappa > \bar{\kappa}$. In particular, it is easy to check that $\frac{\partial \log y}{\partial \log \rho_{f}}$ is a decreasing function with respective to $\kappa$, 64
while \( \frac{\partial \log y}{\partial \log \rho} \) is increasing with \( \kappa \). Therefore, \( \frac{\partial \log y}{\partial \log \rho_f} < \frac{\partial \log \tilde{y}}{\partial \log \rho_f} \) and \( \frac{\partial \log y}{\partial \log \rho_l} > \frac{\partial \log \tilde{y}}{\partial \log \rho_l} \). Therefore when \( d \log \rho_{l,1} < 0 \) and \( d \log \rho_{f,1} < 0 \),

\[
\Delta_{y_1} (\rho_{f,1}) > 0, \tag{131}
\]

\[
\Delta_{y_1} (\rho_{l,1}) < 0. \tag{132}
\]

Note that \( \frac{\partial \log y}{\partial \log \kappa} < 0 \), \( \frac{\partial \log \kappa}{\partial \log \rho_f} < 0 \) and \( \frac{\partial \log \kappa}{\partial \log \rho_l} > 0 \), it is straight forward to show that

\[
\Delta_{y_1} (\rho_{f,1}) < 0, \tag{133}
\]

\[
\Delta_{y_1} (\rho_{l,1}) > 0. \tag{134}
\]

**Proof of Lemma 6** The aggregate saving function of followers is given by

\[
m_{f,t+1} = \beta (1 + r) m_{f,t} + \frac{\alpha}{\gamma} p_{f,t} y_{f,t}, \tag{135}
\]

which implies that, around steady state,

\[
d \log m_{f,t+1} = \beta (1 + r) d \log m_{f,t} \tag{136}
\]

\[
+ [1 - \beta (1 + r)] d \log p_{f,t} \tag{137}
\]

\[
+ [1 - \beta (1 + r)] d \log y_{f,t}. \tag{138}
\]

Substitute out \( \frac{dp_{f,t}}{y_{f,t}} \), it gives that

\[
\frac{dm_{f,t+1}}{m_f} = \frac{dm_{f,t}}{m_f} + [1 - \beta (1 + r)] \frac{\gamma}{\alpha} \frac{dp_{f,t}}{p_f} \tag{139}
\]

\[- [1 - \beta (1 + r)] (1 - \alpha) \frac{\gamma}{\alpha} \frac{dw_t}{w}. \tag{140}
\]

Combining with \( \frac{dp_{f,t}}{p_f}, \frac{dp_{l,t}}{p_l}, \frac{d\kappa_t}{\kappa} \) and \( \frac{d\rho_{f,t}}{\rho_f} \), one can find that

\[
\frac{dm_{f,t+1}}{m_f} = \frac{2 (1 - \alpha) (\epsilon - 1) + \kappa + 1 + 2 (1 - \alpha) \beta (1 + r) (1 + \kappa) \frac{\gamma}{\alpha} \frac{dm_{f,t}}{m_f}}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1) \frac{d\kappa_t}{\kappa}} \tag{141}
\]

\[+ [1 - \beta (1 + r)] \frac{\gamma}{\alpha} \frac{2 (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1) \frac{d\rho_{f,t}}{\rho_f}}{\kappa} \tag{142}
\]

\[+ [1 - \beta (1 + r)] \frac{\gamma}{\alpha} \frac{2 (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1) \frac{d\rho_{f,t}}{\rho_f}}{\kappa} \tag{143}
\]

\[+ [1 - \beta (1 + r)] \frac{\gamma}{\alpha} \frac{2 (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1) \frac{d\rho_{f,t}}{\rho_f}}{\kappa}. \tag{144}
\]
Therefore, together with the equation (125), the elasticities in the definition of \( \Delta m_{j,t} \) and \( \Delta m_{j,t}^2 \) are given by

\[
\frac{\partial \log m_{\rho_l}'}{\partial \log \rho_f} = \left[1 - \beta (1 + r)\right] \gamma \frac{\kappa}{\alpha} + 2 (1 - \alpha) \left(\frac{1}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)\right),
\]

\[
\frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f} = \left[1 - \beta (1 + r)\right] \gamma \frac{2 (1 - \alpha)}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1),
\]

\[
\frac{\partial \log m_{\rho_f}'}{\partial \log \rho_l} = \frac{\beta (1 + r) 2 (1 - \alpha) (1 + \kappa) \alpha}{2 (1 - \alpha)} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1),
\]

\[
\frac{\partial \log \kappa}{\partial \log m_f} = -\frac{\frac{\partial \log \kappa}{\partial \log \rho_f} \frac{\partial \log m_f}{\partial \log \rho_l} \frac{d \log \rho_f}{d \log \rho_l}}{1 + \frac{\partial \log \rho_f}{\partial \log \rho_l} \frac{\partial \log \rho_f}{\partial \log \rho_l}}.
\]

Consider the case that the condition (50) satisfies. For the direct effect, i.e. \( \sum_{t=2}^{\infty} \Delta_{m,t}^1 (\rho_{j,t}) \) for \( j \in \{l, f\} \). Proof by mathematical induction.

1. When \( t = 2 \), it is easy to check that \( \frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f} > 0 \) and a decreasing function of \( \kappa \). Meanwhile, \( \frac{\partial \log m_{\rho_l}'}{\partial \log \rho_l} < 0 \) and is an increasing function of \( \kappa \). Note that \( \kappa > \kappa \), it implies that

\[
0 < \frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f} < \frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f}, \quad (150)
\]

\[
0 > \frac{\partial \log m_{\rho_l}'}{\partial \log \rho_l} > \frac{\partial \log m_{\rho_l}'}{\partial \log \rho_l} \quad (151)
\]

Therefore with \( d \log \rho_{j,1} < 0 \),

\[
0 > \frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f} d \log \rho_{f,1} > \frac{\partial \log m_{\rho_f}'}{\partial \log \rho_f} d \log \rho_{f,1}, \quad (152)
\]

\[
0 < \frac{\partial \log m_{\rho_l}'}{\partial \log \rho_l} d \log \rho_{l,1} < \frac{\partial \log m_{\rho_l}'}{\partial \log \rho_l} d \log \rho_{l,1}, \quad (153)
\]

or,

\[
\Delta_{m,1}^1 (\rho_{f,1}) > 0, \quad (154)
\]

\[
\Delta_{m,1}^1 (\rho_{l,1}) < 0. \quad (155)
\]
2. When $t \geq 2$, suppose that

$$
0 > \left( \frac{\partial \log m'_f}{\partial \log m_f} \right)^{t-1} \frac{\partial \log m'_f}{\partial \log \rho_f} \, d \log \rho_{f,1} > \left( \frac{\partial \log \bar{m}'_f}{\partial \log \bar{m}_f} \right)^{t-1} \frac{\partial \log \bar{m}'_f}{\partial \log \rho_f} \, d \log \rho_{f,1}, \tag{156}
$$

$$
0 < \left( \frac{\partial \log m'_f}{\partial \log m_f} \right)^{t-1} \frac{\partial \log m'_f}{\partial \log \rho_t} \, d \log \rho_{t,1} < \left( \frac{\partial \log \bar{m}'_f}{\partial \log \bar{m}_f} \right)^{t-1} \frac{\partial \log \bar{m}'_f}{\partial \log \rho_t} \, d \log \rho_{t,1}. \tag{157}
$$

Since $\frac{\partial \log m'_f}{\partial \log m_f}$ is a decreasing function with respect to $\kappa$, or,

$$
\frac{\partial \log \bar{m}'_f}{\partial \log \bar{m}_f} > \frac{\partial \log m'_f}{\partial \log m_f} > 0, \tag{158}
$$

it must have

$$
0 > \left( \frac{\partial \log m'_f}{\partial \log m_f} \right)^{t} \frac{\partial \log m'_f}{\partial \log \rho_f} \, d \log \rho_{f,1} > \left( \frac{\partial \log \bar{m}'_f}{\partial \log \bar{m}_f} \right)^{t} \frac{\partial \log \bar{m}'_f}{\partial \log \rho_f} \, d \log \rho_{f,1}, \tag{159}
$$

$$
0 < \left( \frac{\partial \log m'_f}{\partial \log m_f} \right)^{t} \frac{\partial \log m'_f}{\partial \log \rho_t} \, d \log \rho_{t,1} < \left( \frac{\partial \log \bar{m}'_f}{\partial \log \bar{m}_f} \right)^{t} \frac{\partial \log \bar{m}'_f}{\partial \log \rho_t} \, d \log \rho_{t,1}, \tag{160}
$$

or

$$
\Delta^1_{m_f,t}(\rho_{f,1}) > 0, \tag{161}
$$

$$
\Delta^1_{m_f,t}(\rho_{t,1}) < 0. \tag{162}
$$

Therefore, for all $t \geq 1$, it turns out that $\Delta^1_{m_t}(\rho_{f,1}) > 0$ and $\Delta^1_{m_t}(\rho_{t,1}) < 0$, which implies that

$$
\sum_{t=1}^{\infty} \Delta^1_{m_f,t}(\rho_{f,1}) > 0, \tag{163}
$$

$$
\sum_{t=1}^{\infty} \Delta^1_{m_f,t}(\rho_{t,1}) < 0. \tag{164}
$$

For the indirect effect, similarly we although show the proof with mathematical induction.

1. When $t = 1$, since $\frac{\partial \log m'_f}{\partial \log \kappa} > 0$, $\frac{d \log \kappa}{d \log \rho_f} < 0$ and $\frac{d \log \kappa}{d \log \rho_t} > 0$,

$$
0 > \left( \frac{\partial \log m'_f}{\partial \log \rho_f} + \frac{\partial \log m'_f}{\partial \log \kappa} \, d \log \kappa \right) \, d \log \rho_{f,1} > \left( \frac{\partial \log \bar{m}'_f}{\partial \log \rho_f} \right) \, d \log \rho_{f,1}, \tag{165}
$$

$$
0 < \left( \frac{\partial \log m'_f}{\partial \log \rho_t} + \frac{\partial \log m'_f}{\partial \log \kappa} \, d \log \kappa \right) \, d \log \rho_{t,1} < \left( \frac{\partial \log \bar{m}'_f}{\partial \log \rho_t} \right) \, d \log \rho_{t,1}, \tag{166}
$$
or,
\[
\Delta^2_{m_{t_1}}(\rho_{f,1}) > 0, \quad (167)
\]
\[
\Delta^2_{m_{t_1}}(\rho_{l,1}) < 0. \quad (168)
\]

2. When \( t \geq 2 \), suppose that \( \Delta^2_{m_{f,t}}(\rho_{f,1}) > 0 \) and \( \Delta^2_{m_{f,t}}(\rho_{l,1}) < 0 \). Note that

\[
0 < \frac{\partial \log m'_f}{\partial \log m_f} + \frac{\partial \log m'_f}{\partial \log \kappa} \frac{d \log \kappa}{d \log m_f} < \frac{\partial \log \tilde{m}'_f}{\partial \log m_f}, \quad (169)
\]

it must be that

\[
\Delta^2_{m_{f,t+1}}(\rho_{f,1}) > 0, \quad (170)
\]
\[
\Delta^2_{m_{f,t+1}}(\rho_{l,1}) < 0. \quad (171)
\]

Therefore, for all \( t \geq 1 \), it turns out that \( \Delta^2_{m_{f,t}}(\rho_{f,1}) > 0 \) and \( \Delta^2_{m_{f,t}}(\rho_{l,1}) < 0 \), which implies that

\[
\sum_{t=1}^{\infty} \Delta^2_{m_{f,t}}(\rho_{f,1}) > 0, \quad (172)
\]
\[
\sum_{t=1}^{\infty} \Delta^2_{m_{f,t}}(\rho_{f,1}) < 0. \quad (173)
\]

**Proof of Lemma 7**

By the definition of \( \Upsilon_t \),

\[
\Upsilon_t = v_t + \frac{1}{1 + r} \pi_{l,t+1} (\tilde{v}_{t+1} - v_{t+1}) + \frac{1}{1 + r} \frac{\pi_{l,t+1}}{\pi_{l,t}} \Upsilon_{t+1}. \quad (174)
\]

Given that \( \kappa_t = \frac{1}{1 - \Upsilon_t} \), it implies that the Euler equation of the leader takes the form that

\[
(1 - \kappa_t^{-1})^{-1} = v_t + \frac{1}{1 + r} \frac{\pi_{l,t+1}}{\pi_{l,t}} (\tilde{v}_{t+1} - v_{t+1}) + \frac{1}{1 + r} \frac{\pi_{l,t+1}}{\pi_{l,t}} (1 - \kappa_{t+1}^{-1})^{-1}. \quad (175)
\]

Therefore, at steady state,

\[
\Upsilon = v + \frac{\tilde{v}_1}{r}, \quad (176)
\]

where

\[
v = \epsilon - (\epsilon - \sigma) \left[ 1 + (\mu_t^{-1} - 1) \frac{\sigma + \frac{a}{\alpha} - 1}{\epsilon + \frac{a}{\alpha} - 1} \right]^{-1}, \quad (177)
\]
\[
\tilde{v}_1 = -\frac{\partial y_l}{\partial m_f} \frac{\partial m'_f}{\partial p_f} \frac{\partial p_f}{\partial p_l} \frac{\partial p_l}{\partial m_f}, \quad (178)
\]
In further, taken $p$, $y$ as given, the differentiation of equation (28), (26) and (27) gives

$$\frac{\partial p_f}{\partial p_l} = \frac{(\epsilon - \sigma) \mu_l}{\epsilon + \frac{\gamma}{\alpha} - 1 - (\epsilon - \sigma) \mu_f}. \quad (179)$$

The differentiation of equation (30) implies that

$$\frac{\partial m_f'}{\partial p_f} = \frac{\gamma}{\alpha} \left[ 1 - \beta (1 + r) \right]. \quad (180)$$

Taken $p_l$, $y$, $p$ and $w$ as given, applying the implicit function theorem to the differentiation of equation (26), (28), (29) and (27), we can find that

$$\frac{\partial y}{\partial m_f} = \frac{- (\epsilon - \sigma) \mu_f}{\epsilon + \frac{\gamma}{\alpha} - 1 - (\epsilon - \sigma) \mu_f}. \quad (181)$$

**Proof of Lemma 8** Log-linearization of equation (173) and $(1 - \kappa^{-1})^{-1} = \Upsilon$, we can derive the system of difference equations as follows.

$$\begin{bmatrix} \frac{dX_{t+1}}{dX_t} \end{bmatrix} = \begin{bmatrix} x_{11} & x_{12} \\ x_{21} & x_{22} \end{bmatrix} \begin{bmatrix} \frac{dX_t}{dX_t} \\ \frac{dX_t}{dX_t} \end{bmatrix}, \quad (182)$$

where

$$x_{21} = \frac{\frac{dX_{t+1}}{dX_t}}{\frac{dX_t}{dX_t}} > 0, \quad (183)$$

$$x_{22} = \frac{\frac{dX_{t+1}}{dX_t}}{\frac{dX_t}{dX_t}} \in (0, 1), \quad (184)$$

$$x_{11} = \frac{1}{1 + r} \left( \frac{d\hat{v}_1}{d\hat{v}_2} - \frac{d\hat{v}_2}{d\hat{v}_1} \right) \frac{\partial \mu}{\partial m_f} \frac{\partial m_f'}{\partial m_f} + \Upsilon \frac{\kappa^{-1}}{1 - \kappa^{-1}} - \frac{\hat{v}_1}{r} \frac{\partial \pi}{\partial \kappa} + \frac{\hat{v}_2}{r} \frac{\partial \mu}{\partial m_f} \frac{\partial m_f'}{\partial m_f} \frac{\partial m_f'}{\partial m_f} > 0, \quad (185)$$

$$x_{12} = \frac{1}{1 + r} \left( \frac{d\hat{v}_1}{d\hat{v}_2} - \frac{d\hat{v}_2}{d\hat{v}_1} \right) \frac{\partial \mu}{\partial m_f} \frac{\partial m_f'}{\partial m_f} + \frac{\hat{v}_1}{r} \frac{\partial \pi}{\partial \kappa} \left( \frac{\partial m_f'}{\partial m_f} - 1 \right) + \frac{\hat{v}_2}{r} \frac{\partial \mu}{\partial m_f} \frac{\partial m_f'}{\partial m_f} \frac{\partial m_f'}{\partial m_f} \frac{\partial m_f'}{\partial m_f} \frac{\partial m_f'}{\partial m_f} \frac{\partial m_f'}{\partial m_f} > 0, \quad (186)$$

Define

$$f(\lambda) \equiv \lambda^2 - (x_{11} + x_{22}) \lambda + x_{11}x_{22} - x_{12}x_{21} \quad (187)$$
such that the eigenvalue of matrix \[
\begin{bmatrix}
x_{11} & x_{12} \\
x_{21} & x_{22}
\end{bmatrix}
\] are the roots of the function \( f(\lambda) = 0 \). Note that
\[
\frac{x_{11} + x_{22}}{2} > 0
\]
implies that the speed of convergence depends on the root
\[
\lambda^* = \frac{x_{11} + x_{22} - \sqrt{(x_{11} - x_{22})^2 + 4x_{12}x_{21}}}{2}. \tag{188}
\]
In particular, if \( x_{12}x_{21} > 0 \), it implies \( \lambda^* < x_{22} \).

In the case of competitive benchmark, the system can be written as the similar difference equations as
\[
\begin{bmatrix}
\frac{d\kappa_{t+1}}{d\kappa_t} \\
\frac{dm_{f,t+1}}{dm_{f,t}}
\end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 0 & x_{22} \end{bmatrix} \begin{bmatrix}
d\kappa_t \\
dm_{f,t}
\end{bmatrix}, \tag{189}
\]
where the speed of convergence depends on \( x_{22} \).

Therefore, if \( x_{21}x_{21} > 0 \), or \( x_{21} > 0 \), the speed of convergence would be higher in the forward-looking case. Note that it requires that
\[
\frac{\partial m_f}{\partial \mu} \left( \frac{\partial m_f}{\partial \mu} - 1 \right) + \frac{\partial \pi}{\partial \mu} \frac{\partial m_f}{\partial \mu} \left( 1 - \frac{1}{1 + r} \frac{\partial m_f}{\partial \mu} \right) > 0. \tag{190}
\]
A sufficient condition is that \( \frac{d\kappa}{dt} < 0 \), or,
\[
\epsilon > \xi \equiv (\mu_l^{-1} - 1) \left( \sigma + \frac{\gamma}{\alpha} - 1 \right) - \left( \frac{\gamma}{\alpha} - 1 \right). \tag{191}
\]
Furthermore, denote \( \varrho_1 \) and \( \varrho_2 \) such that
\[
\frac{dm_{f,t+1}}{m_f} = \varrho_1 \frac{dm_{f,t}}{m_f}, \tag{192}
\]
\[
\frac{d\kappa_t}{\kappa} = \varrho_2 \frac{dm_{f,t}}{m_f}. \tag{193}
\]
Substitute into the system of equations (182), it turns out that the speed of convergence \( \varrho_1 \) is the root of the function
\[
\varrho_1^2 - (x_{11} + x_{22}) \varrho_1 + x_{11}x_{22} - x_{12}x_{21} = 0. \tag{194}
\]
Let \( \varrho_1 = \lambda^* \). When \( x_{12}x_{21} > 0 \), it must be that
\[
\varrho_2 = \frac{\lambda - x_{22}}{x_{12}} < 0, \tag{195}
\]
which implies, not only the faster convergence, but also \( \frac{d \log \kappa_t}{d \log m_{f,t}} < 0 \): the sign of indirect effect remains consistent as in Lemma 6.

At \( t = 1 \), for \( k \in \{L, F\} \), log-linearization over the Euler Equation gives the system

\[
\begin{bmatrix}
\frac{d \kappa_2}{\kappa} \\
\frac{d \log m_{f,2}}{m_f}
\end{bmatrix} =
\begin{bmatrix}
u_{11} & \nu_{12,k} \\
\nu_{21} & \nu_{22,k}
\end{bmatrix}
\begin{bmatrix}
\frac{d \kappa_1}{\kappa} \\
\frac{d \log \rho_{1}}{\rho}
\end{bmatrix},
\]

(196)

where

\[
u_{11} = x_{11},
\]

(197)

\[
u_{12,k} = \frac{1}{1+r} \left( \frac{\hat{\sigma}_L}{\hat{\sigma}_f} - \frac{\hat{\sigma}_u}{\hat{\sigma}_f} \right) \frac{\partial \log \rho_{1}}{\partial \kappa} + \frac{\hat{\sigma}_L}{\hat{\sigma}_f} \frac{\partial \kappa}{\partial \kappa} - \frac{\hat{\sigma}_u}{\hat{\sigma}_f} \frac{\partial \kappa}{\partial \rho} + \frac{\hat{\sigma}_u}{\hat{\sigma}_f} \frac{\partial \rho}{\partial \rho} + \frac{\hat{\sigma}_L}{\hat{\sigma}_f} \frac{\partial \rho}{\partial \rho}
\]

(198)

\[
u_{21} = \frac{\partial \kappa}{\partial \kappa} > 0,
\]

(199)

\[
u_{22,k} = \frac{\partial \kappa}{\partial \rho}.
\]

(200)

Consider the shock \( d \log \rho_{f,1} < 0 \) and \( d \log \rho_{l,1} < 0 \) separately.

1. When \( d \log \rho_{f,1} < 0 \), it must be that \( d \log m_{f,2} < 0 \), \( d \log \kappa_2 > 0 \). Note that

\[
d \log \kappa_2 - \nu_{12,F} d \log \rho_{1,F} = \nu_{11} d \log \kappa_1,
\]

(201)

a sufficient condition such that \( d \log \kappa_1 > 0 \) is that \( \nu_{12,F} > 0 \), or

\[
\left( \frac{1}{1+r} \frac{\hat{\sigma}_L}{\hat{\sigma}_f} \frac{\partial \log \rho_{1}}{\partial \kappa} + \frac{\hat{\sigma}_L}{\hat{\sigma}_f} \frac{\partial \kappa}{\partial \kappa} - \frac{\hat{\sigma}_u}{\hat{\sigma}_f} \frac{\partial \kappa}{\partial \rho} + \frac{\hat{\sigma}_u}{\hat{\sigma}_f} \frac{\partial \rho}{\partial \rho} + \frac{\hat{\sigma}_L}{\hat{\sigma}_f} \frac{\partial \rho}{\partial \rho} \right) > 0.
\]

(202)

Given that
\[
\frac{\partial \mu}{\partial \rho F} = \frac{(1 - \epsilon) \left(1 + \alpha\right)}{2 \left(1 + \alpha\right) \left(1 - \alpha\right)} \frac{\gamma}{\alpha} + \kappa + 1 + 2 \left(1 - \alpha\right) \left(\epsilon - 1\right),
\]
(203)

\[
\frac{\partial \mu}{\partial m F} = \frac{(1 - \epsilon) \left(1 + \alpha\right)}{2 \left(1 + \alpha\right) \left(1 - \alpha\right)} \frac{\gamma}{\alpha} + \kappa + 1 + 2 \left(1 - \alpha\right) \left(\epsilon - 1\right),
\]
(204)

\[
\frac{\partial m'_F}{\partial m F} = \frac{\left[1 - \beta \left(1 + r\right)\right] \frac{\gamma}{\alpha} \left[\kappa + 1 + 2 \left(1 - \alpha\right) \left(\epsilon - 1\right)\right]}{2 \left(1 + \alpha\right) \left(1 - \alpha\right)} \frac{\gamma}{\alpha} + \kappa + 1 + 2 \left(1 - \alpha\right) \left(\epsilon - 1\right),
\]
(205)

\[
\frac{\partial \pi}{\partial \rho F} = \frac{\gamma}{\alpha} \frac{\partial m F}{\partial \rho F},
\]
(206)

it must be that

\[
\frac{\partial \mu}{\partial \rho F} < \frac{\partial \mu}{\partial m F} \frac{\partial m'_F}{\partial \rho F},
\]
(207)

\[
\frac{\partial \pi}{\partial \rho F} < \frac{\partial \pi}{\partial m F} \frac{\partial m'_F}{\partial \rho F}.
\]
(208)

Therefore, the inequality (202) holds true.

2. When \(d \log \rho_{L,1} < 0\), it must be that \(d \log m_{F,2} > 0\), \(d \log \kappa_2 < 0\). Note that

\[
d \log \kappa_2 - u_{12} d \log \rho_{1,F} = u_{11} d \log \kappa_1,
\]
(209)

a sufficient condition such that \(d \log \kappa_2 < 0\) is that \(u_{12,L} < 0\), or

\[
\frac{1}{1 + r} \frac{d \hat{v}}{d \hat{\mu}} \left(\frac{d \mu}{d \mu} \frac{d m'_F}{d \mu} - \frac{d \mu}{d \rho_i} \frac{d m_i}{d \rho_i}\right) + \hat{v} \frac{d \mu}{d \mu} \left(\frac{d \mu}{d \rho_i} - \frac{1}{1 + r} \frac{d \mu}{d \rho_i} \frac{d m'_i}{d \rho_i}\right) < 0, \quad \text{negative}
\]
(210)
Given that

\[
\frac{\partial \mu}{\partial \mu} = \frac{(\epsilon - 1) \left[ (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} + \kappa + 1 \right]}{2 (1 - \alpha) (1 + \kappa) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)}, \tag{211}
\]

\[
\frac{\partial m_F}{m_F} = \frac{(1 - \epsilon) (1 - \alpha) (1 + \kappa)}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)}, \tag{212}
\]

\[
\frac{\partial m'_F}{m_F} = \frac{[1 - \beta (1 + r)] \frac{\gamma}{\alpha} [\kappa + 1 - 2 (1 - \alpha) (\epsilon - 1)]}{2 (1 + \kappa) (1 - \alpha) \frac{\gamma}{\alpha} + \kappa + 1 + 2 (1 - \alpha) (\epsilon - 1)}, \tag{213}
\]

\[
\frac{\partial \pi}{\partial \pi} > -\frac{\partial \pi}{\partial m_F}, \tag{214}
\]

it must be that

\[
\frac{\partial \mu}{\partial \mu} > \frac{\partial m_F}{m_F} \frac{\partial m'_F}{m_F} \frac{\partial \pi}{\partial \pi} > -\frac{\partial \pi}{\partial m_F} \frac{\partial \pi}{\partial \pi}. \tag{215}
\]

Therefore, the inequality (210) holds true.

Combining the two cases, it implies that for the forward-looking leader, \( \frac{d \log \kappa_1}{d \log \rho_{1,F}} > 0 \), \( \frac{d \log \kappa_1}{d \log \rho_{1,L}} < 0 \). The signs of the elasticity shown in Lemma 4 remain consistent with that of the myopic leader.
